Received 10 June 1997/Accepted 26 November 1997

The utility of the present generation of recombinant adenovirus vectors for gene therapy applications could potentially be improved by designing targeted vectors capable of gene delivery to selected cell types in vivo. In order to achieve such targeting, we are investigating the possibilities of incorporation of ligands in the adenovirus fiber protein, which mediates primary binding of adenovirus to its cell surface receptor. Based on the proposed structure of the cell-binding domain of the fiber, we hypothesized that the HI loop of the fiber knob can be utilized as a convenient locale for incorporation of heterologous ligands. In this study, we utilized recombinant fiber proteins expressed in baculovirus-infected insect cells to demonstrate that the incorporation of the FLAG octapeptide into the HI loop does not ablate fiber trimerization and does not disturb formation of the cell-binding site localized in the knob. We then generated a recombinant adenovirus containing this modified fiber and showed that the short peptide sequence engineered in the knob is compatible with the biological functions of the fiber. In addition, by using a ligand-specific antibody, we have shown that the peptide incorporated into the knob remains available for binding in the context of mature virions containing modified fibers. These findings suggest that heterologous ligands can be incorporated into the HI loop of the fiber knob and that this locale possesses properties consistent with its employment in adenovirus retargeting strategies.
the knob tertiary structure. Clearly, 3D structural information has important bearing upon the placement of heterologous protein sequences within the knob for targeting purposes. Such localization of targeting ligands would ideally be achieved in such a manner as to allow their surface presentation and to minimally perturb the fiber quaternary structure. Thus, the recent crystallization of the fiber knob by Xia et al. (47, 48) has provided a level of structural resolution potentially allowing such a rational modification of the fiber protein. According to the proposed 3D model of the knob (Fig. 1), the HI loop possesses a number of features which predict its utility as an alternative site for ligand incorporation. Specifically, the HI loop does not contribute to intramolecular interactions in the knob. Therefore, incorporation of additional protein sequence should not affect the trimerization of the fiber. In addition, the loop consists mostly of hydrophilic amino acid residues and is exposed outside the knob. It thus potentially demonstrates a high degree of flexibility, creating an optimal environment for ligand incorporation. Furthermore, the lengths of HI loops vary significantly in knobs of different adenovirus serotypes. This fact suggests that alterations of the original structure of the loop, such as insertions and deletions, should be compatible with the correct folding of the entire knob domain. Finally, the HI loop is not involved in the formation of the putative cell-binding site localized in the knob.

Based on these considerations, we endeavored to develop a novel approach to modify the adenovirus fiber protein by employing the HI loop of the knob for this purpose. We show in this report that it is possible to incorporate heterologous amino acid sequences into the HI loop without affecting the correct folding of the fiber polypeptide and its biological functions. Further, our results suggest that this locale may offer advantages for strategies designed to achieve tropism modification based on genetic alteration of capsid proteins.

MATERIALS AND METHODS

Cells. 293 cells (15) obtained from Microbix (Toronto, Ontario, Canada) and HeLa human adenocarcinoma cells and A549 human lung carcinoma cells obtained from the American Type Culture Collection (Rockville, Md.) were maintained in Dulbecco’s modified Eagle’s medium (DMEM)-Ham’s F12 from Mediatech (Herndon, Va.) supplemented with 10% fetal calf serum (FCS) (HyClone Laboratories, Logan, Utah) at 37°C and 5% CO2.

Enzymes. Restriction endonucleases, T4 DNA ligase, T4 polynucleotide kinase, and proteinase K were from either New England Biolabs (Beverly, Mass.) or Boehringer Mannheim (Indianapolis, Ind.).

Protein assay. The concentrations of purified proteins were determined by the Bradford protein assay (Bio-Rad, Hercules, Calif.) with bovine gamma globulin as the standard.

Antibodies. Antifiber monoclonal antibodies 4D2 (18) and 1D6.14 (14) were generated at the University of Alabama at Birmingham Hybridoma Core Facility. Anti-FLAG monoclonal antibody M2 and M2-affinity gel were purchased from Scientific Imaging Systems (Eastman Kodak, New Haven, Conn.).

FIG. 1. 3D model of the Ad5 fiber knob. The trimer forms a propeller-like structure when it is viewed along the threefold-symmetry axis from above. The HI loop, exposed outside the knob, connects the β-strands H and I, which are involved in the formation of the cell-binding site. (Reproduced from reference 47 by permission.)
Maizei et al. (29) with a conversion factor of 1.1 × 10³ viral particles per absorbance unit at 260 nm. To determine the titer of infectious viral particles on 293 cells, a plaque assay was employed as described by Mittereder et al. (33). Recombinant baculoviruses expressing chimeric fibers were generated with a Bac-to-Bac expression system from Gibco-BRL (Life Technologies) according to the manufacturer’s protocol.

Expression and purification of six-His-tagged recombinant proteins. Recombinant fibers were expressed in Spodoptera frugiperda Sf9 cells infected with recombinant baculovirus by the method recommended for the Bac-to-Bac system (Life Technologies). Recombinant proteins were then purified by immobilized metal ion affinity chromatography on Ni-NTA HisSorb Strips (Qiagen) essentially as described in the Qiagen manual. Briefly, 200 µl of fiber protein solution at a concentration of 1 µg/ml was added to each well of an Ni-NTA HisSorb Strip and incubated for 1 h at room temperature. After incubation, the wells were washed four times with phosphate-buffered saline (PBS)–Tween buffer, and 200 µl of anti-fibronectin antibody (1:2,000 dilution) or anti-FLAG antibody (1:140 dilution) was added. Following incubation at room temperature for 2 h, the wells were washed again and incubated with 1:10,000 dilution of goat anti-mouse immunoglobulin G conjugated to horseradish peroxidase (HRP) for 45 min. The wells were then washed four times with PBS-Tween buffer and developed with 2′,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) (diammonium salt). The ABTS-HRP reaction was read at a wavelength set at 405 nm.

FLAG accessibility assay. To demonstrate the binding of the FLAG-tagged fiber protein incorporated into intact virions of Ad5FLAG to anti-FLAG M2 monoclonal antibody, an immunoprecipitation assay was employed. Ad5FLAG and Ad2/Luc recombinant baculoviruses were incubated with anti-FLAG M2 monoclonal antibody (1:10,000 dilution) at 4°C for 2 h and washed again at 4°C on a rotating wheel. Following incubation, the gel was spun down by brief centrifugation in a microcentrifuge. The supernatant was collected for further analysis, and the pellet was washed with 0.5 ml of Tris-buffered saline. Virus was eluted at 4°C with 50 µl of Tris-buffered saline containing 400 µg of FLAG peptide per ml. The supernatant containing unbound material, the wash, and the eluate were then employed to detect the presence of the virus. For this, aliquots of these fractions were treated for 1 h at 37°C with sodium dodecyl sulfate (SDS), EDTA, and protease K at final concentrations of 1%, 10 mM, and 100 µg of protein per 10⁶ viral particles. The samples were analyzed by agarose gel electrophoresis to detect viral DNA.

Purification of the fiber-FLAG protein by immunoprecipitation. The recombinant fiber-FLAG protein was expressed in baculovirus-infected Sf9 cells as follows. For large-scale expression of the fiber-FLAG protein, monolayers of Sf9 cells in T75 flasks were infected with recombinant baculovirus at a multiplicity of infection of 5 to 10 and then were incubated at 28°C until a complete cytopathic effect was observed. The infected cells were harvested by low-speed centrifugation, and resuspended in lysis buffer containing 50 mM Tris-HCl (pH 7.4), 10 mM MgCl₂, and 0.5% bovine serum albumin (BSA), and the mixture was then incubated overnight at 4°C on a rotating wheel. Following incubation, the gel was spun down by brief centrifugation in a microcentrifuge. The supernatant was collected for further analysis, and the pellet was washed with 0.5 ml of Tris-buffered saline. Virus was eluted at 4°C with 50 µl of Tris-buffered saline containing 400 µg of FLAG peptide per ml. The supernatant containing unbound material, the wash, and the eluate were then employed to detect the presence of the virus. For this, aliquots of these fractions were treated for 1 h at 37°C with sodium dodecyl sulfate (SDS), EDTA, and protease K at final concentrations of 1%, 10 mM, and 100 µg of protein per 10⁶ viral particles, respectively. The samples were analyzed by agarose gel electrophoresis to detect viral DNA.

Trimerization assay of recombinant proteins. To determine whether the fiber proteins expressed in baculovirus-infected insect cells could form trimers, these proteins were analyzed by SDS-polyacrylamide gel electrophoresis as previously described (31). Proteins were either boiled prior to electrophoresis, to dissociate the trimers, or loaded on the gel without denaturation. The trimeric or monomeric configuration of these molecules was thus determined based on their mobilities in the gel.

Inhibition of virus-mediated gene transfer by recombinant fiber proteins. The ability of the chimeric fiber-FLAG chimeras to block adenovirus-mediated gene transfer was evaluated in infection inhibition experiments similar to those described previously (16, 25, 35, 38). Briefly, monolayers of HeLa cells grown in a 24-well plate were preincubated at room temperature with serial 10-fold dilutions of either wild-type fiber or fiber-FLAG protein prior to infection with a replication-defective recombinant adenovirus expressing luciferase, AdCMVlacZ. After the 2 h adsorption period, the unbound virus was washed, and the cells were incubated at 37°C to allow internalization of AdCMV Lac and expression of the luciferase gene. A luciferase assay of the lysates of infected cells was performed 20 h postinfection with a luciferase assay system from Promega (Madison, Wis.).

Virus binding assay. Human lung carcinoma A549 cells were grown in T75 flasks and then harvested with EDTA, washed once with PBS, pelleted, and resuspended to a final concentration of 10⁸ cells/ml in DMEM-Ad medium (DMEM, 20 mM HEPES, 0.5% BSA) as described by Wickham et al. (45). One-hundred-microliter aliquots of the cells were transferred to 5-ml test tubes and incubated for 1 h at 4°C with 100 µl of recombinant fiber protein diluted in DMEM-Ad medium.

The recombinant adenoviruses AdCMVlacZ and Ad5FHIFLAG were purified on a CsCl gradient and dialyzed against buffer containing 10 mM HEPES, 1 mM MgCl₂, and 0.5% glycerol (pH 7.4). Aliquots of both viruses containing 50 µg of viral protein were labeled with 125I with IODO-BEADS iodination reagent (Pierce, Rockford, Ill.) as previously described (20). Labeled virions were purified from unincorporated 125I by gel filtration on PD-10 columns (Pharmacia, Piscataway, N.J.). Fifty-microliter aliquots of labeled virions with total radioactivities of 10⁶ cpm were then added to A549 cells preincubated with fiber dilutions or PBS and incubated at 4°C for another hour. The samples were diluted with 4 ml of PBS containing 0.1% BSA, and the cells were pelleted by centrifugation. Supernatants containing unbound virus was aspirated, and the radioactivities of cell pellets were determined in a gamma counter.

RESULTS

Characterization of recombinant fibers expressed in baculovirus-infected insect cells. To test the concept of the suitability of the HI loop of the fiber knob for incorporation of heterologous protein sequences, we first employed recombinant fiber proteins expressed in a baculovirus expression system. This system has already proved its utility for the expression of functional Ad2, Ad3, and Ad5 fiber proteins, as well as Ad3-Ad5 and Ad5-Ad3 fiber chimeras (13, 27, 34, 38).

To achieve this aim, we used a PCR approach to derive a gene encoding the Ad5 fiber knob with a partial deletion in the HI loop. This deletion was engineered to remove amino acids TLNGTQETGDTTP from the HI loop of the fiber knob domain and to introduce a unique EcoRV site in place of the deleted sequence, thereby facilitating the cloning of alternative sequences in this region (Fig. 2). The deletion removed the portion of the HI loop which varies most significantly in the fiber knobs of different serotypes of human adenoviruses. The sequence generated by PCR contained an open reading frame corresponding to two segments of the fiber protein including amino acids glycine-387 through isoleucine-534 and serine-548 through glutamine-581 (coordinates given are according to those of the wild-type Ad5 fiber protein sequence). This sequence was cloned into the plasmid vector pOE30. The newly generated plasmid, pOE.KNOBωHI, was then utilized as a cloning vector to incorporate a fragment of DNA encoding the FLAG octapeptide (DYKDDDDK), which has been widely used as a detection and purification tag in a variety of studies. Thus, we chose to exploit this FLAG peptide in our fiber constructs as a probe to determine whether a heterologous peptide sequence incorporated into the HI loop of the knob was accessible in the context of a trimeric fiber molecule. By incorporating this sequence into the open reading frame of the knob, we also restored the previously deleted codons. Therefore, in the newly generated plasmid, pOE.KNOBωωFLAG, the FLAG coding sequence was introduced as insertions between threonine-546 and proline-547. This plasmid was then employed to construct a full-size recombinant fiber gene in a baculovirus transfer vector. A similar transfer plasmid containing the wild-type fiber gene was designed for control purposes. In order to facilitate subsequent purification of the expression products, we introduced into the designs of both genes a sequence encoding an amino-terminal six-His tag. These plasmids were then utilized to generate two recombinant baculoviruses containing fiber genes encoding wild-type Ad5 fiber and a fiber protein containing FLAG peptide in the HI loop of the fiber knob domain.

Recombinant fibers were recovered from the lysates of baculovirus-infected insect cells with Ni-NTA–Sepharose designed for purification of the six-His-tagged proteins. The yield of purified fibers was in the range of 10 µg of protein per 10⁶ infected cells. Analysis by SDS-polyacrylamide gel electro-
phoresis of both recombinant proteins showed that they formed stable trimers which, when boiled in the gel loading buffer, dissociated into monomers of the expected molecular mass of 63 kDa (Fig. 3A). This result demonstrated that the incorporation of a short peptide sequence in the HI loop of the knob does not ablate trimerization of the fiber. Therefore, by using the baculovirus expression system we were able to obtain preparative amounts of the recombinant fibers of interest which were suitable for subsequent assays.

Accessibility of the FLAG peptide in the context of trimeric fiber. To find out whether the FLAG peptide introduced into the HI loop of the fiber was available for binding, we used an assay based on the specific interaction of the FLAG-tagged proteins with an affinity matrix containing anti-FLAG monoclonal antibody. For these experiments, the recombinant fiber protein with the FLAG sequence in the HI loop (fiber-FLAG) was purified on an Ni-NTA–Sepharose column and then immunoprecipitated with M2-affinity gel. Protein bound to the matrix was then specifically eluted with FLAG peptide and analyzed on an SDS-containing polyacrylamide gel (Fig. 3B). According to this analysis, the fiber-FLAG protein efficiently bound to M2-affinity gel, demonstrating the availability of the FLAG epitope for interaction with an anti-FLAG monoclonal antibody in the context of the trimeric fiber molecule. Importantly, this interaction did not affect the stability of the trimer, suggesting that a recombinant virion containing a novel ligand incorporated in the HI loop of the fiber knob will maintain its structural integrity throughout the binding step of the infection.

Inhibition of adenovirus infection by recombinant fiber-FLAG protein. Since we did not expect the FLAG peptide to possess the ability to target adenovirus to a novel cellular receptor, it was necessary to determine whether the incorporation of this peptide in the HI loop affected proper folding of the cell-binding site localized in the fiber knob. If the hypothesis that the HI loop is not involved in the formation of this site were incorrect and if fiber-FLAG could not bind to the fiber receptor on the cell surface, further attempts to rescue the virus containing this recombinant fiber would inevitably fail. To address these issues, we employed a fiber-FLAG recombinant protein to block adenovirus infection in the in vitro setting. This established assay is based on the fact that recombinant adenovirus fiber proteins are capable of blocking infection by the adenovirus from which they were derived. In addition, this inhibition of viral infection takes place in a dose-dependent manner.

In our experiments, HeLa cells seeded in 12-well tissue culture plates were preincubated with various concentrations of...
FIG. 4. Inhibition of adenovirus infectivity by recombinant fiber proteins. HeLa cells were preincubated with either the wild-type (wt) fiber or fiber-FLAG at the indicated concentrations for 10 min at room temperature. AdCMVLuc was then added at a multiplicity of infection of 10, and incubation was continued for another 30 min at room temperature. The bound virus was aspirated, complete medium was added, and the cells were transferred to 37°C. After 30 h, the cells were lysed and luciferase activity was determined. Luciferase activities are given as percentages of the activity in the absence of blocking fiber protein. Each point represents the mean of four determinations obtained in one experiment.

As seen in Table 1, both fiber proteins efficiently reacted with anti-fiber antibodies 4D2 and 1D6.14, thereby suggesting that the 3D structure of the knob in the fiber-FLAG molecule is identical to that of the wild-type fiber. In addition, the fiber-FLAG chimera specifically reacted with anti-FLAG antibody M2, confirming the availability of this epitope for binding in the context of a trimeric fiber molecule. Thus, these results validated the data generated earlier by gel electrophoresis analysis of Ni-NTA- or M2-affinity gel-purified fiber-FLAG protein, providing the rationale for the incorporation of the fiber-FLAG chimera into the adenovirus virion for further characterization.

**Generation of Ad5F_FHFLAG.** Despite the fact that the data obtained with the recombinant fiber-FLAG protein supported the concept of its functional utility in the context of the adenovirus virion, only successful generation of the recombinant virus would prove our hypothesis regarding the compatibility of the modifications of the HI loop of the fiber knob with viral functions. Therefore, we undertook the task of incorporating the fiber-FLAG chimera into the adenovirus virion.

In order to derive this virus, a novel genetic method based on homologous DNA recombination in *E. coli* cells was utilized (7). In brief, this method involves recombination between two linear DNA molecules cotransformed into bacterial cells to generate a recombinant adenovirus genome. One of these molecules is plasmid pTG3602, or its derivative, containing the full-size adenovirus genome cloned in the bacterial vector and flanked with two *PacI* sites. The second partner in this recombination schema is the genetic construct of interest flanked with two segments of adenovirus genomic DNA which dictate the localization of this construct in the adenovirus genome generated as a result of the recombination. This DNA sequence can be either a transgene or the original Ad5 gene, modified by traditional methods of genetic engineering in the context of small recombinant plasmids. To reduce the nonrecombinant background generated by pTG3602, prior to transformation this plasmid was cleaved with a restriction enzyme within or near the region of the genome where the final construct was going to be inserted. Although this method has numerous advantages compared to traditional generation of recombinant adenovirus genomes by homologous recombination in mammalian cells, it requires the existence of unique restriction sites within the regions of the adenovirus genome to be modified. However, Ad5 genomic DNA in pTG3602 does not contain any unique restriction sites in the fiber gene, which limits its utility for modifications of fiber. Thus, to overcome this limitation, we modified this plasmid by inserting a unique cleavage site for the restriction endonuclease *SwaI* into the fiber gene. To this end, one of the two *NdeI* sites present in Ad5 DNA and localized 47 bp downstream from the fiber gene’s 5’ end was converted into an *SwaI* site by insertion of an *SwaI* linker (Fig. 5). The plasmid generated, pVK30, was then utilized for homologous recombination with the fragment of DNA containing the gene encoding fiber-FLAG flanked with viral DNA adjacent to the fiber gene in the Ad5 genome.

*Values are means ± standard deviations of results obtained in two independent experiments.*
result of this recombination, a plasmid, pVK300, containing a modified fiber gene in the context of the complete adenovirus genome was derived. Adenovirus DNA was released from pVK300 by *PacI* digestion and used for transfection of 293 cells to rescue the virus as described previously (7).

DNA isolated from CsCl gradient-purified virions of the newly generated virus, Ad5F<sub>H</sub>FLAG, was subjected to PCR analysis and cycle sequencing to confirm the presence of the FLAG coding sequence in the fiber gene incorporated in the genome. According to both analyses, Ad5FH<sub>H</sub>FLAG indeed contained the fiber gene of interest.

Characterization of Ad5F<sub>H</sub>FLAG by a cell-binding assay. The yield of Ad5F<sub>H</sub>FLAG grown on 293 cells, approximately 10<sup>11</sup> PFU per preparation obtained from 20 75-cm<sup>2</sup> tissue culture flasks, was comparable to what we normally obtain when growing the wild-type Ad5. Also, we did not see any delay in infection dynamics when rescuing the virus or when expanding it. These observations suggested that the introduction of the FLAG peptide in the HI loop of the knob did not significantly affect the correct folding of the fiber molecule and its biological functions.

In order to prove this, we employed radiolabeled Ad5F<sub>H</sub>FLAG to investigate its ability to bind the fiber receptors on the cell surface. In this assay, <sup>125</sup>I-labeled Ad5F<sub>H</sub>FLAG (B) labeled with <sup>125</sup>I were added to samples, and incubation was continued for an additional hour. The cells were washed with 4 ml of PBS containing 0.1% BSA and pelleted by low-speed centrifugation. Radioactivities of samples were determined with a gamma counter. Each point represents the mean of two determinations obtained in one experiment.

![FIG. 6. Adenovirus binding assay](image)
dose responses when competing with fibers of either type. Thus, incorporation of the heterologous peptide in the HI loop of the fiber-FLAG protein did not have any negative effect on the formation of the cell-binding site localized in the knob and, therefore, did not affect virus infectivity.

**FLAG accessibility in the context of the Ad5FHIFLAG virion.** Since the ultimate goal of our efforts is the insertion of a targeting ligand into the knob, it was necessary to determine whether such a ligand would be available for interaction with its target cell surface receptor after its incorporation into the adenovirus virion. To this end, we employed the FLAG sequence incorporated into the fiber of Ad5FHIFLAG to test the accessibility of the HI loop of the knob in the context of an intact adenovirus particle. This was accomplished in an assay similar to the one used to evaluate FLAG accessibility in the recombinant fiber-FLAG protein expressed in insect cells. Virions purified on a CsCl gradient were dialyzed against HEPES buffer and incubated with M2-affinity gel to allow interaction between the FLAG peptide and an anti-FLAG monoclonal antibody conjugated to the gel matrix. Similarly prepared virions of AdCMVLuc containing wild-type fibers were utilized in this experiment as a negative control. After incubation, the buffer containing unbound material was collected and the gel was washed with the buffer to remove the traces of free virus. Finally, the viruses were eluted from the gel with soluble FLAG peptide. Aliquots of the samples collected were treated with proteinase K to release viral DNA from virions, which was then visualized by agarose gel electrophoresis (Fig. 7). As expected, virions of AdCMVLuc did not react with M2 antibody and were detected only in the fraction containing unbound virus and in the wash. In marked contrast, Ad5FHIFLAG particles efficiently bound to the M2-affinity gel, since viral DNA was present primarily in the FLAG peptide eluate. Thus, our findings have established that the heterologous ligand sequence engineered into the HI loop of the knob domain of the fiber incorporated in the intact Ad5 virion remains accessible for interaction with the relevant receptor structure, thereby providing the rationale for the generation of genetically targeted adenovirus vectors on this basis.

**DISCUSSION**

Despite the numerous attempts which have been made to improve adenovirus as a vector for gene therapy applications, it still suffers from a number of important disadvantages, one of them being the promiscuous tropism of this virus. Genetic modification of adenovirus coat proteins to target novel cell surface receptors is the most radical and, if successful, potentially the most efficient way to overcome this limitation. In this regard, fiber, penton base, and hexon proteins are candidates for such genetic modifications. While modifications of the penton base (42, 46) and the hexon (8, 11) have been reported, these alterations were limited to the introduction of short peptide sequences into the exterior domains of these components of the adenovirus virion. In contrast, a larger number of studies have attempted functional modifications of the fiber protein. These attempts to modify the fiber protein have an obvious explanation: in contrast to the hexon and penton base proteins, the fiber protein mediates the primary interaction of the virus with its cognate cellular receptor and therefore dictates the tropism of the virus. In addition, due to its rod-like structure, the fiber can optimally expose a novel binding ligand engineered into its structure, thus providing efficient binding to an alternative cellular receptor. Thus, altering to the carboxy-terminal knob domain of the fiber normally containing the cell-binding site is a logical approach to modifying viral tropism.

Since the time this idea was originally employed (31), several groups of investigators have proved its utility. To this end, recombinant adenoviruses containing chimeric Ad5-Ad3 (25, 37) fiber were derived, demonstrating the possibility of creating functional fiber chimeras. In addition, it was shown that by replacing the knob domain of the fiber, one can alter the receptor specificity of the virus. Furthermore, in an elegant study by Wickham et al. (45), addition of a carboxy-terminal polysyline sequence to the fiber polypeptide resulted in expanded tropism of the adenovirus vector. Recently, recombinant adenoviruses with fibers containing carboxy-terminal gastrin-releasing peptide (30a), somatostatin, E-selectin-binding peptide, and six-His sequence (24a) have been generated. However, it should be noted that some of these efforts have addressed the goal of ablating the native tropism of the adenovirus vector; in these approaches, novel tropism distinct from the preexisting natural tropism of the vector was engineered.

Until recently, the ability to accomplish the practical design of retargeted adenovirus vectors was limited by two major problems: lack of knowledge of the structure of the fiber knob domain and difficulty in manipulating the fiber gene in the context of the adenovirus genome. In this regard, publication of the 3D model of the Ad5 fiber knob by Xia et al. (47, 48) and the development of a novel genetic method by Chartier et al. (7), which allow modification of virtually any region of the adenovirus genome, will dramatically facilitate efforts to retarget the adenovirus via alterations to the knob domain of the fiber. Thus, the present study is the first attempt to exploit our expanded knowledge regarding the fiber structure, as well as new technological breakthroughs in generating recombinant adenovirus genomes, to derive adenovirus vectors with modified fibers containing novel peptide ligands. In this report we describe the utilization of the HI loop of the fiber knob as an
alternative site for incorporation of heterologous peptide sequences. According to the 3D model of the Ad5 fiber knob, the HI loop does not contribute to interactions within the knob which stabilize its trimeric configuration and is not involved in the formation of the receptor-binding site. Importantly, due to the prevalence of hydrophilic amino acid residues in its primary sequence, the HI loop is exposed outside the knob, thereby facilitating the interaction of potential ligand with the cellular receptor.

For initial proof of this concept, we incorporated a FLAG coding sequence into the region of the fiber gene corresponding to the HI loop and expressed this modified gene in baculovirus-infected insect cells. An amino-terminal six-His tag incorporated into the design was used for simple chromatographic purification of recombinant fiber protein. Baculovirus-directed expression of this recombinant full-size fiber was efficient, and according to our gel analysis and ELISA with the trimer-specific anti-fiber monoclonal antibody, the product of expression was trimeric.

To further characterize the fiber-FLAG protein produced in insect cells, we demonstrated the accessibility of FLAG in the context of the fiber trimer. For this we employed an assay based on the specific interaction of FLAG-tagged proteins with M2-affinity gel containing anti-FLAG monoclonal antibody. This analysis confirmed that the FLAG peptide is localized on the surface of the trimeric knob and is available for binding, thereby supporting the hypothesis about surface localization of the HI loop. By employing the fiber-FLAG chimera to block adenovirus infection, we have also shown that insertion of the FLAG peptide into the HI loop of the knob does not affect the correct folding of the cell-binding domain localized in the knob. This is a significant finding, considering that the HI loop connects β-strands H and I, which are hypothesized to be involved in binding to the cellular receptor (47, 48).

To incorporate fiber-FLAG chimeras into the adenovirus virion, we generated a recombinant adenovirus genome by using a novel method described recently (7). To reach this end, we modified a master plasmid, pTG3602, obtained from Transgene to engineer a vector which greatly facilitates modifications of the fiber gene in the adenovirus genome. By using this plasmid, we generated a recombinant genome and rescued the virus of interest, Ad5FHIFLAG. Importantly, this new virus is produced in high yields and demonstrates dynamics of infection identical to those of the wild-type Ad5. Successful rescue of Ad5FHIFLAG, as well as subsequent characterization of the virion, confirmed our conclusions based on the results obtained with fiber-FLAG protein expressed in baculovirus-infected insect cells, thereby making baculovirus an expression system of choice for further fiber-modeling experiments.

Thus, we have proved that the HI loop of the fiber knob is a convenient site for incorporation of heterologous peptide ligands which may be successfully utilized in order to target adenovirus vectors for gene therapy applications. This location on the virion can be used either as an alternative site or in addition to carboxy-terminal modifications of the fiber protein, offering a unique loop-like environment, which may be required for proper biological functioning of some ligand sequences. For example, this structure may be beneficial for peptide ligands obtained from phage display libraries containing random peptide sequences flanked with two cysteine residues forming a disulfide bridge (23, 24). In addition, ligands with the loop-like configuration may be less susceptible to degradation by cellular carboxypeptidases than ligands positioned at the carboxy terminus of the fiber. To realize the full potential of the HI loop for ligand incorporation, we have experiments in progress to make recombinant adenoviruses containing different targeting moieties in this locale. Generation of recombinant adenoviruses containing fibers with targeting ligands incorporated into the HI loop of the knob will facilitate further efforts towards an improved adenovirus vector for gene therapy applications. Although the development of novel methods for the purification of adenoviruses was not the focus of our study, successful use of the FLAG epitope in our binding experiments suggests that this or a similar purification tag can be incorporated into an adenovirus virion to facilitate its purification. This simple purification technique does not require expensive laboratory equipment such as ultracentrifuges or high-pressure liquid chromatography systems and can be easily scaled up if needed. The utility of this method for purification of recombinant adenoviruses remains to be examined.
