Received 2 September 1997/Accepted 15 December 1997

Defective interfering viral particles are readily produced in cell culture after a high multiplicity of infection with many animal RNA viruses. Due to defects that they carry in their genomes, their life cycle needs to be complemented by the helper functions provided by a parental virus which makes them both dependent on and competitive with the parental virus. In many instances, this may cause the abrogation of a lytic cycle of the parental virus, leading to a persistent infection. In this paper, we describe for the first time the presence of truncated or defective interfering viral RNAs produced in Vero cells persistently infected with the flavivirus Murray Valley encephalitis virus. While these RNAs have not been detected in acutely infected Vero cells, their appearance coincided with the establishment of persistent infection. We also show for the first time that the defective viral RNAs replicate well in both cell culture and cell-free virus replication systems, indicating that they may interfere with the replication of parental virus at the level of viral RNA synthesis. Significantly, structural analyses of these RNA species including nucleotide sequencing have revealed that they carry similar nucleotide deletions encompassing the genes coding for the prM and E proteins and various gene segments coding for the N terminus of the NS1 protein. These deletions are in frame, allowing the synthesis of truncated NS1 proteins to occur in persistently infected cells. This may have further implications for the interference with the parental virus at the level of viral RNA synthesis in addition to a major one at the level of virion assembly and release.

Viral persistence in vivo and in vitro has been reported for a number of animal RNA and DNA viruses. Two major strategies have been employed by these viruses to establish and maintain a persistent infection: one which involves the evasion of the host immune surveillance by the virus by using a variety of tactics to either remove recognition molecules on infected cells or abrogate lymphocyte and/or macrophage functions and the other which alters viral replication and transcription, resulting in nonlytic infection with the production of incomplete or defective viruses (3, 23, 24).

Defective interfering (DI) viruses were initially described for influenza virus by von Magnus (29), who observed their production in embryonated chicken eggs after infection with a large inoculum. They have been also reported for other RNA virus families, including picornaviruses, alphaviruses, and flaviviruses (1, 18, 26). Structural analyses of DI viral genomes revealed that the majority of them are deletion mutants which originate from the genome of parental virus. Although essential replication and encapsidation signals are preserved, DI viruses usually lack part or most of their protein-encoding sequences, which makes them highly dependent upon the parental virus for both replication and encapsidation factors. The competition for these factors between defective and parental viruses affects the replication of parental virus, which eventually leads to a reduction in the titers of infectious parental virus (16). It has also been proposed that DI viruses may play a significant role in the establishment and maintenance of persistent infection (17).

The ability to establish persistent infection in vivo and in vitro has been previously reported for many flaviviruses, including yellow fever (21), St. Louis encephalitis (27), Japanese encephalitis (26), tick-borne encephalitis (13), West Nile (3, 11), and Murray Valley encephalitis (MVE) viruses (24). The cause of persistence in some of the persistent flavivirus infections described so far has been suggested to be the production of DI viral particles, which interfered with the replication of parental virus (3, 24, 26). It has recently been reported that the persistent infection with the Japanese encephalitis virus may also be attributed to the presence of a truncated viral protein NS1 in the absence of any detectable DI virus (6).

Flaviviruses are positive single-stranded RNA viruses with linear RNA genomes of approximately 11 kb. They have a single open reading frame, the 5′ portion of which encodes three structural proteins, i.e., the capsid (C), membrane (M), and envelope (E) proteins, and the 3′ portion of which encodes seven nonstructural proteins, designated NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5. While the role of all structural proteins is known and several nonstructural proteins such as NS2B, NS3, and NS5 have been shown to be involved in the virus polyprotein processing and RNA synthesis (2, 4), the functions of the remaining nonstructural proteins, including the NS1 protein, have not been fully characterized. These viruses use a unique strategy of replication involving double-stranded RNAs such as a replicative form (RF), which serves as the template for the synthesis of virion RNA, and a replicative intermediate (RI), which carries nascent genomic RNA (7, 9). It has been shown that similar viral RNA species are produced during acute infection regardless of the system used to study flavivirus replication, whether in cell culture, in a...
cell-free system of an RNA-dependent RNA polymerase (RDRP) assay, or in mouse brains in vivo (2, 7, 9, 28). In this study, we sought to characterize the viral RNA species produced in persistently infected Vero cells with MVE virus by an RDRP assay, Northern blot analysis, and reverse transcription (RT)-PCR. Here we describe for the first time the presence of truncated viral RNAs in Vero cells persistently infected with MVE virus. These defective viral RNAs may be responsible for the establishment of persistent infection in vitro by interfering with the lytic cycle of the parental virus.

MATERIALS AND METHODS

Cells and media. African green monkey kidney (Vero) cells were maintained in growth medium consisting of M199 medium supplemented with 10% fetal calf serum (FCS) and L-glutamine. The cells were subcultured weekly by standard trypsinization techniques. Vero cells used for virus propagation were maintained in a minimal growth medium supplemented with 2% FCS and l-glutamine. The cells were subcultured weekly by standard trypsinization techniques. Vero cells used for virus propagation were maintained in a minimal growth medium supplemented with 2% FCS and l-glutamine. The cells were subcultured weekly by standard trypsinization techniques. Vero cells used for virus propagation were maintained in a minimal growth medium supplemented with 2% FCS and l-glutamine.

Virus. A standard virus stock of the Australian flavivirus MVE virus, strain OR2 (19), was obtained from the departmental collection as a 10% homogenate of infected suckling mouse brain and was propagated twice in Vero cell monolayers at a multiplicity of infection (MOI) of 0.1. The cell monolayers were incubated at 37°C for 1 h with the virus, and then the inoculum was replaced with fresh medium and the cultures were incubated at 37°C for an additional 72 h or until a cytopathic effect (CPE) was visible. The cell culture medium containing the infectious virus was then harvested, clarified by centrifugation at 1,000 × g, and aliquoted into aliquots before storage at −70°C. Acute infection of Vero cells was similarly performed at an MOI of 0.5 or 1.0.

Virus titration. The titration of the infectious virus in the cell culture medium was performed by 50% tissue culture infective dose (TCID₅₀) assay in serial 10-fold dilutions in Vero cells as described previously (25).

Establishment of a persistent infection. A confluent Vero cell monolayer was infected with MVE virus strain OR2 at an MOI of 10 for 1 h at 37°C. After infection, the medium was replaced, and the cells were maintained in culture until extensive CPE occurred. Lysed cells and medium were removed and replaced with fresh M199 medium supplemented with 10% FCS and l-glutamine. The remaining viable cells grew back, resulting in persistently infected, confluent monolayers. The cells were passaged by trypsinization every 4 to 5 days. The cell culture medium from Vero cells persistently infected with the MVE virus was collected at every passage from passages 1 to 10 (P1 to P10), clarified by centrifugation at 1,000 × g, and used as a template for RT-PCR analysis using the Titan one-tube RT-PCR system (Boehringer Mannheim). The same strain of MVE virus free of any DI virus particles was propagated in laboratory mice. Viral RNA was isolated from mouse brains as described by Urosevic et al. (28) and used as a positive control. The RT-PCR mixture contained 0.5 to 1.0 µg of RNA in a total volume of 50 µl. The reaction mixture consisted of 50 mM Tris-HCl (pH 8.3), 75 mM KCl, 2.5 mM MgCl₂, 0.3 mM each of dNTPs, 1 unit of reverse transcriptase, 200 units of Taq polymerase, and 80 pmol of each primer. The program consisted of an initial denaturation step at 95°C for 5 min followed by 35 cycles of 95°C for 1 min, 55°C for 1 min, and 72°C for 1 min. The PCR products were analyzed on nonnaturating agarose gels as described previously.

Immunofluorescence studies. Acutely and persistently infected cultures of Vero cells were fixed with acetone at −20°C and probed with a mixture of monoclonal antibodies directed against the NS1, prM, and E proteins of the MVE virus (Amer), which were then incubated with a goat anti-mouse antibody conjugated to fluorescein (TAGO) for 1 h at room temperature. Fluorescence was observed by a Leitz fluorescence microscope.

Preparation of cell extracts. Cell extracts were prepared from both acutely and persistently infected Vero cells with MVE virus strain OR2 at 24 h or 5 to 6 days postinfection (p.i.), respectively, as described previously (7). Cell extracts were harvested over several passages of persistently infected Vero cells, from P1 to P10. Briefly, cell monolayers were harvested and washed in 1× phosphate-buffered saline and then resuspended in 10 mM Tris-Cl (pH 8.0) containing 10 mM sodium acetate (TN buffer) at a concentration of 4 × 10⁶ cells/ml. Membrane particles were disrupted by passing the cells 20 times through a 21-gauge needle and then 20 times through a 26-gauge needle. The cell lysates were centrifuged at 14,000 × g for 5 min, and the supernatants (cytoplasmic fractions) were collected and stored at −70°C. The cell extracts were either used in cell-free virus replication assays, i.e., the RDRP assays, or extracted by phenol to isolate RNA for Northern blot analysis. Protein concentrations in the cell extracts were determined by using a Micro BCA protein assay reagent kit (Pierce).

RDRP assay. RDRP assays were carried out by using the extracts of infected Vero cells which had been stored at −70°C. The standard assay contained 50 mM Tris-HCl (pH 8.0), 100 mM NaCl, 8 mM MgCl₂, 75 µM D-phenylalanine, 10 mM 2-mercaptoethanol, 5 mM phosphoenolpyruvate, 3 U of pyruvate kinase (Boehringer Mannheim) per ml, 0.5 mM each CTP, UTP, and ATP, 25 µM GTP, 5 µCi of [α-32P]GTP, and the cellular extract containing 5 to 8 mg of cellular proteins per ml. The assays were carried out at 37°C for 2 h or until a cytopathic effect (CPE) was visible. The cell culture medium containing the infectious virus was then harvested, clarified by centrifugation at 1,000 × g, and used as a template for RT-PCR analysis using the Titan one-tube RT-PCR system (Boehringer Mannheim).

RT-PCR. Phenol-extracted samples from persistently infected Vero cells were used as a template for RT-PCR analysis using the Titan one-tube RT-PCR system (Boehringer Mannheim). The same strain of MVE virus free of any DI virus particles was propagated in laboratory mice. Viral RNA was isolated from mouse brains as described by Urosevic et al. (28) and used as a positive control. The RT-PCR mixture contained 0.5 to 1.0 µg of RNA in a total volume of 50 µl. The reaction mixture consisted of 50 mM Tris-HCl (pH 8.3), 75 mM KCl, 2.5 mM MgCl₂, 0.3 mM each of dNTPs, 1 unit of reverse transcriptase, 200 units of Taq polymerase, and 80 pmol of each primer. The program consisted of an initial denaturation step at 95°C for 5 min followed by 35 cycles of 95°C for 1 min, 55°C for 1 min, and 72°C for 1 min. The PCR products were analyzed on nonnaturating agarose gels as described previously.

Cloning and sequencing. RT-PCR products were excised from the agarose gel and purified with a JETquick gel extraction kit (Genom). Purified RT-PCR products were either used directly for sequencing or cloned into a pGEM-T vector (Promega) and used to transform competent XL1 Blue cells. Positive clones were confirmed by PCR by using the same conditions described above and prepared for sequencing. Both plasmid DNA obtained by a modified mini alkaline lysis-polyethylene glycol precipitation procedure (Applied Biosystems) and RT-PCR products obtained as described above were subjected to sequencing with an ABI PRISM dye terminator cycle sequencing kit (Perkin-Elmer) in the presence of either primer K2Ls, K1Ls, or 3018s (Table 2) and analyzed by using an ABI 373A automated DNA sequencer (Applied Biosystems).

Western blot analysis. Polycrylamide gel electrophoresis (PAGE) was used to separate 15 to 20 µg of protein present in cytoplasmic lysates of Vero cells persistently infected with MVE virus. This was performed in parallel with lysates from cells acutely infected with the same virus and mock-infected cells. Samples were either boiled for 5 min or not boiled in nonreducing sample buffer (62.5 mM Tris-HCl [pH 6.8], 10% glycerol, 0.025% bromophenol blue) before loading. Following PAGE, the proteins were transferred to a nitrocellulose membrane and treated with blocking buffer as described elsewhere (14). The membranes were incubated with a cocktail of monoclonal antibodies to NS1 (1:1 [vol/vol] dilution in culture supernatant), M2-10C6, M6-6E, M2-SC4, and M2-824 (15, overnight at 4°C) in nonreducing-launched antigen. Goat anti-mouse immunoglobulin G (Bio-Rad) were used as a secondary antibody detected at 37°C for 2 h or until a cytopathic effect (CPE) was visible. The cell culture medium containing the infectious virus was then harvested, clarified by centrifugation at 1,000 × g, and used as a template for RT-PCR analysis using the Titan one-tube RT-PCR system (Boehringer Mannheim).

1/1,000. Blots were stained with diaminobenzidine (0.05% in phosphate-buffered saline with 0.018% H\textsubscript{2}O\textsubscript{2}) until the desired intensity was obtained and then rinsed in distilled water before being photographed (15).

RESULTS

Establishment of persistent infection in Vero cells with MVE virus. A persistent infection of Vero cells with MVE virus strain OR2 was established by infecting the cells at an MOI of 10. Three to five days later, 80 to 90% of the cells showed severe CPE and were detached from the monolayer, while the surviving cells continued to grow to confluence and were routinely passaged up to 10 times. The cell culture medium from each passage was collected and titrated for infectious virus by TCID\textsubscript{50} assay (Table 1). As shown in Table 1, the viral titers of the surviving cells continued to grow to confluence, showed severe CPE and were detached from the monolayer, virus strain OR2 was established by infecting the cells at an MOI of 10, and the cell culture medium was collected and titrated for infectious virus by TCID\textsubscript{50} assay (Table 1). This has been assumed to be a result of interference with the lower dilutions (10^-2 and 10^-3) of the cell supernatants from the persistently infected cells did not produce CPE in indicator cell monolayers during the TCID\textsubscript{50} assay (data not shown).

To confirm the presence of virus in persistently infected cells, an indirect immunofluorescence assay using a mixture of virus-specific monoclonal antibodies to the viral proteins NS1, preM, and E (15) was carried out. This assay revealed the presence of MVE virus antigens in approximately 40 to 60% of the cells in persistently infected cultures at P1 compared to 100% of the cells acutely infected with parental virus at a lower input dose (MOI of 1) (Fig. 1). Although the acutely infected cells showed an extensive presence of viral proteins, the intensity of the positive signal in those cells was much lower than that in persistently infected cells, indicating the presence of smaller amounts of viral proteins (Fig. 1).

Replication of defective viral RNA in persistently infected cells. To study the viral RNA species produced during persistent infection of Vero cells with MVE virus, cell extracts were harvested from persistently infected cells at P1 to P10 and analyzed by an RDRP assay. Initially, the RDRP assay was performed in the absence of label and the viral RNA products were analyzed by Northern blot hybridization after separation on an agarose gel under nondenaturing conditions (Fig. 2A). By this approach, the total viral RNAs produced in both cell culture during virus infection and RDRP assay during cell-free virus replication in either persistently or acutely infected Vero cells were determined. As shown before by using a similar approach to study total viral RNA produced in the mouse brain (28), Northern blot analysis revealed the presence of three standard viral RNA species in the acutely infected cells: virion RNA (vRNA), RF RNA, and RI RNA (Fig. 2A, lane 2). However, persistently infected cells showed two additional viral RNA species which migrated faster than the standard RF and vRNA species (Fig. 2A, lane 1). As will be shown later, these faster-migrating RNAs contain large internal deletions. Also, at this stage, we were not able to distinguish how many individual defective viral RNA species were present in the broad bands shown in Fig. 2A due to resolution limitations of agarose gel electrophoresis. It will be shown later by using RT-PCR and nucleotide sequencing that there are at least four defective viral RNA species which comigrated in the gels shown in Fig. 2 and 3. Hence, the RNAs present only in persistently infected cells are labelled defective RF (dRF) and defective vRNA (dvRNA) in Fig. 2 and subsequent figures. The identity of the RF and vRNA forms, both standard and defective, was confirmed by oligonucleotide hybridization in which the oligonucleotide probe complementary to the viral negative-strand RNA (Table 2; primer 10,006s) hybridized to RI and both standard and defective RFs, while the oligonucleotide probe complementary to the viral positive-strand RNA (Table 2; primer 440as) hybridized to all viral RNA species, including RI, standard and defective RFs, and standard and defective vRNAs (data not shown).

The standard RDRP assay was also performed in the presence of [\alpha-32P]GTP with cellular extracts of either acutely or persistently infected cells from all passages to detect viral RNA species which are replicated de novo under the cell-free conditions. Under such conditions, the dRF species was obvious in indicator cells superinfected at P1 compared to P10, and the viral titers in persistently infected cells from all passages to detect viral RNA species which are replicated de novo under the cell-free conditions. Under such conditions, the dRF species was observed only in persistently infected cells (Fig. 3A, lanes 2 to 11). The appearance of the respective standard and dvRNAs was observed after a longer exposure (data not shown). If the defective viral RNA described above has accumulated as a result of the high MOI of the virus used to produce a persistent infection in Vero cells (MOI of 10), then diluting the medium collected from the persistently infected cells containing the defective virus should have the opposite effect on the accumulation of defective RNA. This hypothesis was tested by the following experiment in which neat cell culture medium and two dilutions (10^-2 and 10^-3) of it obtained from persistently infected cells at P1 (medium 1 [M1]) were used to acutely infect the fresh monolayers of Vero cells. To achieve the acute infection of Vero cells with viral stocks containing defective virus, neat, 10^-2-diluted, and 10^-3-diluted M1 was used in aliquots 50 times smaller than those previously employed in the TCID\textsubscript{50} assay (Table 1). The second round of cell culture medium (M2) was collected from acutely infected cells 3 to 5 days p.i. with either neat, 10^-2-diluted, or 10^-3-diluted M1 at the time of the CPE appearance and used to either titrate infectious virus by TCID\textsubscript{50} or infect fresh monolayers of Vero cells for the preparation of cellular extracts for the RDRP assay. Although virus titration revealed similar amounts of infectious virus in M2 medium regardless of the dilution of the M1 stock used initially to infect the cells (log_{10} TCID\textsubscript{50} after infection with neat, 10^-2-diluted, and 10^-3-diluted M1 were 6.75, 6.71, and 6.75, respectively), the pattern of interference in the TCID\textsubscript{50} assay was markedly different. No interference was observed at any dilution of M2 collected from the cells infected with a 10^-2 dilution of M1.
FIG. 1. Indirect immunofluorescence of Vero cells infected with MVE virus. A mixture of monoclonal antibodies to the NS1, prM, and E proteins of MVE virus was used to detect the virus in mock-infected Vero cells (A), in Vero cells acutely infected with MVE virus strain OR2 at an MOI of 1 at 24 h.p.i. (B), and in persistently infected Vero cells which survived an acute infection with the same virus at an MOI of 10 and were passaged once (P1) without further addition of the virus (C).
Very low interference was found with the 10^{-2} dilution of M2 collected from cells infected with the 10^{-2} dilution of M1. Interference was observed with the 10^{-1} and 10^{-2} dilutions of M2 obtained from cells infected with the neat M1, as described above (data not shown). The cell extracts obtained 24 h.p.i. with M2 collected from the cell culture infected with the neat M1, as described above, was used in the RDRP assay and, as shown in Fig. 3B (lane 1), displayed de novo synthesis of both RF and dRF species. In contrast, when the cell extracts prepared from Vero cells infected with M2 of cells infected with 10^{-2} (Fig. 3B, lane 2) or 10^{-4} dilution of M1 (Fig. 3B, lane 3) were used in the RDRP assay, no production of dRF was observed. In fact, they resembled the cell extract obtained from the acutely infected cells with the low MOI (MOI of 1) of the parental virus (Fig. 3B, lane 4). A small amount of dRF species could be seen in the cell extract of cells infected with M2 obtained from the cells infected with 10^{-2}, diluted M1 after a longer exposure (data not shown).

**Structural analysis of defective viral RNA.** As shown above, for the first time we have detected fast-migrating viral RNA species in persistently infected cells by use of the RDRP assay in combination with nondenaturing agarose gel electrophoresis and Northern blot hybridization analysis (Fig. 2A, lane 1). To confirm that the viral RNAs identified by this procedure are not artifacts of either the virus RNA isolation procedure or the cell-free replication assay, we have used either the RDRP assay alone (Fig. 3) or direct Northern blot analysis without prior submission to RDRP assay to study total viral RNA in the cell extracts of both acutely and persistently infected cells. By using either approach, similar viral RNA species were revealed to either preexist in cellular extracts (data not shown) or incorporate the label during the RDRP assay (Fig. 3), strongly suggesting that the faster-migrating viral RNA species are genuine products of virus replication. To characterize them further, we decided to use agarose gel electrophoresis under denaturing conditions in combination with Northern blot analysis. These conditions were supposed to resolve whether the fast-migrating, defective viral RNAs were truncated or had an unusually compact conformation. Since the cell-free virus replication assay in the absence of label in combination with Northern blot analysis proved to increase the detection of viral RNAs in the sample (Fig. 2A), we subjected those samples to agarose gel electrophoresis under denaturing conditions (Fig. 2B). Northern blot hybridization with a virus-specific cDNA probe revealed a single RNA species in both persistently and acutely infected cells of 11 kb (Fig. 2B, lanes 1 and 2, respectively), which corresponds to the size of packaged vRNA of the parental virus (Fig. 2B, lane 3), while in persistently infected cells, an additional RNA species of approximately 8 to 9 kb was observed (Fig. 2B, lane 1). This RNA species is likely to be a truncated viral RNA which carries a deletion of approximately 2 to 3 kb.

To determine the position of the deletion in the defective RNA, total RNA isolated from persistently infected cells, containing both parental and defective vRNAs, was hybridized to a panel of oligonucleotide probes that were complementary to the viral genomic sequences and distributed at 1-kb intervals.
passing the deletion, i.e., from positions 215 to 3037. By using primer to amplify a smaller region of the virus genome encompassing positions 1 to 3037 in the virus genome was used in RT-PCR together with the previously used 3018 primer designated K1Ls (Table 2) from the defective RNA of MVE virus strain OR2 (Fig. 4C). In the second attempt, a new primer used in RT-PCR together with the previously used 3018 primer was designed to amplify a smaller region of the virus genome encompassing the deletion, i.e., from positions 215 to 3037. By using this new set of primers, viral RNAs isolated from persistently infected Vero cells at P7 and P8 were subjected to RT-PCR in parallel under the same conditions, and the resulting cDNA products were analyzed by agarose gel electrophoresis (Fig. 4B). As shown in Fig. 4B, a new round of RT-PCR using the new set of primers to amplify viral RNA present in P7 of persistently infected cells has produced a cDNA fragment of 0.55 kb in addition to the expected one of 0.46 kb (lane 1). A parallel RT-PCR performed on the subsequent passage (P8) of persistently infected cells revealed another cDNA product of approximately 0.3 kb in addition to a very strong band of the expected 0.46-kb product and a very faint band of a 0.55-kb fragment (Fig. 4B, lane 2). Four additional cDNA fragments, corresponding to 0.55- and 0.46-kb bands (Fig. 4B, lane 1) and 0.46- and 0.3-kb bands (Fig. 4B, lane 2), were cut out of the gel and subjected to either direct DNA sequencing or cloning into the pGEM-T vector. The cloning resulted in three additional positive clones which, when sequenced, revealed the presence of additional deletions (Fig. 4C). Sequencing of single positive clones for 0.55-, 0.46-, and 0.3-kb products revealed three additional deletions spanning nucleotides 698 to 2955, 462 to 2860, and 459 to 3019 of the MVE virus genome, respectively (Fig. 4C). Direct sequencing of the 0.55- and 0.3-kb RT-PCR products confirmed the presence of the same deletions as those in the corresponding cloned cDNA fragments (data not shown). However, direct sequencing of the 0.46-kb RT-PCR product was not conclusive in the vicinity of the deletion, indicating heterogeneity of the cDNA products (data not shown). This may suggest the presence of additional truncated viral RNA species which carry deletions with a similar size although at slightly different positions. It could be expected from the data described above that the positions of the other deletions may vary from nucleotides 459 to 698 on the left to nucleotides 2839 to 3019 on the right, although the number and sequence of additional defective viral RNA species would be difficult to predict. This may further be complicated by the variability of their occurrence from passage to passage, as already shown for the previously characterized ones (Fig. 4B).

When the sequence data were summarized, four large deletions were revealed which encompass the region of the viral genome from the C terminus of the C protein to the middle of NS1, eliminating a region coding for viral proteins prM and E and the N-terminal portion of NS1 (Fig. 4C). This suggests the presence of at least four distinct although similar defective viral RNAs in persistently infected cells. General features of all four of these deletions are that they are in frame and that their presence and position may not interfere with the synthesis and processing of the viral polyprotein. As an outcome, both shorter polypeptide and truncated NS1 protein may be expected to be produced in persistently infected cells.

**NS1 protein expression in persistently infected Vero cells.** To test the hypothesis described above about the expression and processing of defective polypeptide and expression of different forms of NS1 protein, we have subjected cell lysates from persistently infected Vero cells to Western blot analysis. The samples of mock-infected and acutely and persistently infected Vero cells were separated by 10% PAGE before (Fig. 5) and after boiling in nonreducing sample buffer to allow detection of both dimeric and monomeric forms of NS1 (15). A cocktail of monoclonal antibodies to NS1, M2-10C6, M-E6, M2-SC4, and M2-9A2 (15), has been used in immunoblotting, revealing the presence of two truncated forms of NS1 of approximately 39 and 29 kDa in persistently infected cells, two dimeric forms of 80 and 100 kDa, and one monomeric form of 45 kDa (Fig. 5, lane 3). No additional bands were visible in the sample of persistently infected cells, indicating that truncated

**TABLE 2. Oligonucleotide primers used in Northern blot hybridization and RT-PCR**
NS1 did not form dimers (Fig. 5, lane 3). The same dimeric forms of 80 and 100 kDa and the monomeric form of 45 kDa as those seen in the persistently infected sample were detected in acutely infected cells at 48 h p.i., although no truncated NS1 protein was observed (Fig. 5, lane 2). No reactivity with the monoclonal antibodies was detected in the mock-infected sample (Fig. 5, lane 1).

**DISCUSSION**

In this study, we have analyzed viral RNA molecules involved in the establishment and maintenance of persistent infection with MVE virus strain OR2 in Vero cells. We have used similar experimental conditions to establish persistent infection with MVE virus as previously described (24), although an alternative approach including Northern blot analysis, cell-free virus replication assay, and RT-PCR has been applied to analyze the viral RNA present in persistently infected cells. Using this approach, we were able to identify at least four defective viral RNA species with similar sizes, averaging 8,600 nucleotides. Due to the similarity in their sizes (8,453, 8,615, 8,660, and 8,756 nucleotides), it was not possible to resolve them under the standard agarose gel conditions, either nondenaturing or denaturing, used in our study (Fig. 2 and 3). Their existence and precise position and the size of the deletion they carry were determined by RT-PCR and nucleotide sequencing (Fig. 4). However, their relative abundance...
has been shown to vary from passage to passage, indicating variability in their occurrence (Fig. 4B). These RNAs may either be responsible for or result from the establishment of persistent infection with the normally cytocidal MVE virus. Although some earlier reports suggested the presence of truncated viral RNAs and DI viruses in a cell culture affiliated with persistent flavivirus infection (3, 26), the present study is the first to demonstrate the presence of discrete defective flaviviral RNA species in persistently infected cells. We have also demonstrated for the first time that some of these defective flaviviral RNAs can replicate in both infected cells and a cell-free virus replication system, as revealed by the appearance of their RF(s) in the RDRP assay and Northern blot analysis (Fig. 2 and 3). According to these data, the level of RNA synthesis of the DI viruses is equal to or slightly higher than that of parental virus, indicating that interference may occur at the level of RNA synthesis since it is likely that both defective and parental RNAs use the same replicative machinery. The ability of the defective RNAs to be released from the infected cells together with the parental virus and to infect new cells has also been demonstrated in the set of experiments in which the cell culture medium collected from the persistently infected cells was passaged and used to infect the fresh monolayers of Vero cells. These experiments indicated that the DI viruses present in the cell culture medium of persistently infected cells were able to infect fresh monolayers of Vero cells during an acute infection, replicate and be released into the second-round cell culture medium (M2), preserve their interference capacity in the same dilution range, and persist to the second-round acute infection in which their replication was revealed by the RDRP assay (Fig. 3B, lane 1). With the same set of experiments, we were able to show that the DI viruses could be reduced to undetectable levels by the use of increasing dilutions (10^{-3} and 10^{-2}) of the same cell culture medium (Fig. 3B, lanes 2 and 3). These results are in agreement with the notion that the enrichment of DI viruses is equal to or slightly higher than that of parental RNAs is expressed at the protein level and that, due to the deletions they carry, are incapable of supporting the production of the structural proteins prM and E. This makes defective virus highly dependent on the parental virus for the virion assembly and release from the cell and probably represents the major point of interference with the parental virus. The major feature of the defective viral RNA expression is, as shown in Fig. 5, the appearance of truncated NS1 protein forms, which is in agreement with the expression of the similarly truncated form of the NS1 protein of 39 kDa recently reported to be strongly associated with the persistent infection of a variety of cell types, including Vero cells, with the Japanese encephalitis virus (6). There is also evidence of the existence of similarly truncated NS1 protein in Vero cells acutely infected with the higher dose (MOI of 10) of MVE virus prototype strain 1-51 (15a). The viral NS1 protein has been recently suggested to have an important role in viral RNA replication; this suggestion was based on both its colocalization with the viral RF RNA form in dengue virus- or Kunjin virus-infected cells (20, 30) and the impaired replication of the viral ts mutants of the yellow fever virus carrying the lesions in the NS1 gene (22). The truncation of the NS1 protein may create two different scenarios for the establishment of persistent infection, one in which the DI RNA incapable of producing its own NS1 protein competes with the parental viral RNA for the full-length NS1 and the other in which the truncated form of the NS1 protein has a direct effect on the virus infection as observed by Chen et al. (6), providing an additional, yet-unknown drive to the flavivirus-persistent state. At this stage, we are unable to distinguish between these two scenarios, although evidence presented in this paper strongly supports the hypothesis that the truncated forms of NS1 protein observed in persistently infected cells originate from and are encoded by the defective viral RNAs produced during persistent infection.

The structural defects in flaviviral DI RNAs, as described in this paper, partially resemble those previously detected in a poliovirus system in which naturally occurring deletions were always found to be in frame, which affected the synthesis of structural but not of nonstructural proteins (18). The incorpo-
rati on of an out-of-frame mutation into the poliovirus DI RNA has been shown to abolish the replication of this RNA even in the presence of parental helper virus (14). The ability of the defective viral RNA to be replicated in the presence or absence of parental virus is restored when an in-frame mutation is introduced into the poliovirus genome, suggesting that a cis-acting protein or coupling between translation and replication may be required for poliovirus RNA replication (14). It is our further aim to study the replicon-like properties of the defective viral RNAs described in this paper and the relationship between translation and replication during the replication of flaviviruses.

ACKNOWLEDGMENTS

This work was supported by the Australian Research Council. We thank the staff of the Centre of Molecular and Cellular Biology, University of Western Australia, for the technical assistance with the oligonucleotide synthesis and DNA sequencing. We are especially indebted to R. A. Hall for the monoclonal antibodies to the MVE virus and A. Scalzo for critical comments on the manuscript.
