Hepatitis C virus (HCV) is the leading causative agent of blood-borne chronic hepatitis and is the target of intensive vaccine research. The virus genome encodes a number of structural and nonstructural antigens which could be used in a subunit vaccine. The HCV envelope glycoprotein E2 has recently been shown to bind CD81 on human cells and therefore is a prime candidate for inclusion in any such vaccine. The experiments presented here assessed the optimal form of HCV E2 antigen from the perspective of antibody generation. The quality of recombinant E2 protein was evaluated by both the capacity to bind its putative receptor CD81 on human cells and the ability to elicit antibodies that inhibited this binding (NOB antibodies). We show that truncated E2 proteins expressed in mammalian cells bind with high efficiency to human cells and elicit NOB antibodies in guinea pigs only when purified from the core-glycosylated intracellular fraction, whereas the complex-glycosylated secreted fraction does not bind and elicits no NOB antibodies. We also show that carbohydrate moieties are not necessary for E2 binding to human cells and that only the monomeric nonaggregated fraction can bind to CD81. Moreover, comparing recombinant intracellular E2 protein to several E2-encoding DNA vaccines in mice, we found that protein immunization is superior to DNA in both the quantity and quality of the antibody response elicited. Together, our data suggest that to elicit antibodies aimed at blocking HCV binding to CD81 on human cells, the antigen of choice is a mammalian cell-expressed, monomeric E2 protein purified from the intracellular fraction.

Hepatitis C virus (HCV) is the major cause of chronic hepatitis, which can evolve into cirrhosis, liver failure, or hepatocellular carcinoma (2, 4). There is no vaccine for HCV, and the only available treatment, a combination of alpha interferon and ribavirin, is efficacious in only a minority of patients (33). Given that approximately 200 million chronic HCV infections have been estimated worldwide (52), there is a pressing need to develop new therapies and vaccination strategies. The development of such strategies will be aided greatly by a more complete picture of the structure-function features of HCV proteins.

HCV is an enveloped plus-strand RNA virus of the Flaviviridae family (24). Its genome is 9.5 kb in length with one open reading frame that is translated as a single polyprotein, which is processed by host and virus proteases into at least three structural and seven presumptive nonstructural proteins with various enzymatic activities (5, 22, 47). Two glycoproteins, E1 and E2, are probably virion envelope proteins, containing multiple N-linked glycosylation sites, and form heterodimers in vitro (23, 32, 35, 45). The coexpressed E1-E2 complex localizes to the endoplasmic reticulum (ER) and lacks complex N-linked glycans (7, 8, 13, 15, 45, 49).

Neutralizing antibodies often play a pivotal role in defeating viral infections, including prominent human pathogens such as influenza virus and hepatitis B virus (9, 28). The assessment of neutralizing antibody responses to HCV has been difficult because HCV does not grow efficiently in cell cultures. To overcome this obstacle, we developed a surrogate assay which measures the ability of antibodies to inhibit the binding of recombinant E2 to its putative cellular receptor CD81 on human cells (neutralization-of-binding [NOB] assay) (44, 46). CD81 is a membrane-associated protein belonging to the family of tetraspanins (30). Its large extracellular loop (LEL) binds E2 with a Kd of 1.8 nM (42), and this interaction appears necessary and sufficient for binding of bona fide HCV particles (44). Importantly, chimpanzee sera containing antienvelope antibodies, which are capable of preventing HCV infection in vivo, inhibit the binding of HCV to CD81 in vitro, suggesting that this interaction is relevant to infection (44).

Our research has focused primarily on comparing vaccine formulations of HCV E2, which is an obvious candidate for inclusion in a subunit vaccine because of its potential role in HCV attachment. Thus, targeting antibodies to HCV E2 could be a viable strategy for disrupting the HCV-CD81 interaction. Despite the inherent difficulties in studying HCV infection and the lack of a clear correlate of protection, there is evidence that neutralizing antibodies can be protective. Studies performed with human immunoglobulin (Ig) preparations have suggested some degree of efficacy in preventing the transmission of HCV in the transfusion setting, after liver transplants, and in sexual transmission (17, 27, 43). Relevant data on the existence of HCV-specific neutralizing antibodies also come from experi-
mental vaccination studies in chimpanzees, and in the presence of protease inhibitors and then trichloroacetate precipitated. After

the cutoff, the E2 antigen was detected by Western blotting using anti-E2 antibodies from CHO cell extracts. SDS-PAGE under reducing conditions, the E2 antigen was detected by Western blotting using anti-E2 antibodies from CHO cell extracts. SDS-PAGE under

Cloning, expression, and purification of E2 protein. E2384–661 and E2384–715 were expressed from recombinant CHO cells as described previously (46, 49). For purification of secreted E2 (S-E2), CHO cell conditioned medium was concentrated 23-fold by ultrafiltration and subjected to flowthrough chromatography on a type I ceramic hydroxyapatite (HAP) (Bio-Rad) column equilibrated in 100 mM NaCl–10 mM phosphate (pH 6.3). E2 containing flowthrough fractions, as assessed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and Western blotting, were pooled and concentrated on a 30-kDa cut-off tangular flow filter (Omega membrane; Pall Corp., Torrance, Calif.). Intact (I)-E2 was purified from CHO cells with lysis buffer (4% Triton X-100, 100 mM Tris-HCl [pH 8.0], 1 mM EDTA, protease inhibitors). The solution was loaded on a Galanthus nivalis lectin (Vector Laboratories, Burlingame, Calif.) affinity column equilibrated in 1 M NaCl–2% Triton X-100–50 mM Tris-HCl (pH 8.0). The column was washed with 1 M NaCl–0.1% Triton X-100–20 mM phosphate (pH 6.0) and eluted with 1 M methyl-α-mannoside or endo-

3 Man-linked residues. Endo H cleaves between the two

N-acetylglucosaminidase H (endo H) and blunt-ended NcoI sites of the pAC-E2 constructs. CHO I-E2715 protein at 0.5 m

g/mouse and injection, a total of 100 μl of 1-μg/ml E2-DNA (100 μg) or 50-ng/ml E2-DNA (5 μg) was administered.

Antibody titers. Anti-E2 antibody titers were measured by ELISA. For guinea pig sera, Nunc maxisorb microtiter plates were coated with HeLa E1-E2 antigen (50 ng/ml) and examined for binding to target cells with the help of anti-human Ig. The optical densities were determined in an endpoint dilution assay using a microtiterplate reader.

DNA constructs. The vector pAC-FN used for DNA vaccination was described in detail elsewhere (J. M. Heile, S. Abrignani, and G. Grandi, unpublished data). Briefly, expression of the gene of interest is driven by the human cytomegalovirus immediate-early promoter and enhanced by the simian virus 40 splice site and poly(A) signal. E2 DNA vaccines are derived from a previously described construct, which directs truncated E2aa6-715 of HCV genotype 1a into the ER by a 25-amino-acid (aa) tissue plasminogen activator (TPA)-derived signal sequence (46). The pAC-E2 insert was transferred into the Smal and NotI sites of the pAC-FN polylinker by standard molecular cloning techniques, resulting in pAC-E2-E2. For the construction of DNA vaccines encoding ER-retained E2, the following strategy has been used. pAC-E2-E2 was modified by replacing the C-terminal part of E2 with ER fragments amplified from pMCMV-Hsc5, which encodes the ER as a product from the reticulocyte lobule and is strongly expressed in animal cells. Following transfection, the CHO cells were stained with mAbs and analyzed by flow cytometry.

In vitro analysis of constructs. CHO cells were stably transfected with the E2 DNA vaccines for analysis. Selection was achieved by biotin ex- pression of E2 together with a biotin resistance gene, downstream of the E2 sequence via an internal ribosomal entry site. neo was amplified by PCR from pCDNAneo (Invitrogen) and cloned into BamHI and blunt-ended NotI sites of pCTTE-A2a-1 (Novagen), with NotI and XhoI and blunt ended for insertion into the NotI site of the pAC-E2 constructs. CHO DG44 cells were grown in Ham’s F12 medium supplemented with 10% fetal calf serum, 2 mM L-glutamine, and 0.02% l-proline. Subconfluent monolayers grown in 100-mm diameter dishes were transfected with 20 μg of plasmid DNA by calcium phosphate coprecipitation. Precipitates were incubated with cells for 6 h at 37°C and then given a 3-min shock with 15% glycerol in PBS. Cells were grown for 48 h without selection, divided among 15 plates, and grown for 2 weeks in medium containing 1 mg of G418 (Genetic Research, Cambridge, UK) per ml. All anti-E2 protein was purified from pooled transfecteds without further cloning. Cells were resuspended in lysis buffer (20 mM Tris-HCl [pH 7.5], 100 mM NaCl, 1 mM EDTA, 0.5% NP-40, 0.5% deoxycholate) containing protease inhibitors. E2 was immunoprecipitated with serum of chimpanzees LS59, which was preimmunized with secreted CHO I-E2715 and protected against challenge with homologous HCV (6). Using protein A-Sepharose CL-4B (Pharmacia), the lysate was preclarified with L559 preimmune serum and E2 was precipitated with immune serum. The pellet was resuspended in 100 mM acetic acid (pH 5.0)–0.05% SDS and held for 1 h and then diluted, loaded on a HAP column, and subjected to a concentration step as indicated above. The HAP column was concentrated over a Superose 12 (Pharmacia) gel filtration column equilibrated with phosphate-buffered saline (PBS) (pH 7.0)–1 mM EDTA. Aliquots of collected fractions were trichloroacetate precipitated for analysis. Fractions containing monomers, dimers, and trimers of S-E2715 and I-E2715 were pooled and concentrated as indicated above.

8 Deoxyribonuclease I site and the ochre stop codon, followed by the sequence 5'-CGC CGCGCGTCTGCAAGCAGAAGG-3' (E2715DEL). The resulting constructs are referred to as pAC-E2108, pAC-E2409, pAC-E2509, and pAC-E2715DEL. All PCR-derived modifications were verified using an ABI sequence (Amanum Pharmacia Biotech).

3 aminoterminal region of recombinant HCV E2 protein is the antigen of choice for eliciting the best antibody response in terms of both quality and quantity.

MONOSACCHARIDE CONTENT ANALYSES, DIGESTED E2 WAS TREATED WITH 3 M TRIFLUOROACETIC ACID FOR 6 H AT 100°C TO RELEASE THE MONOSACCHARIDES. FOLLOWING HYPOXYLATION, SAMPLES WERE DERIVATIZED AT pH 8.0 WITH 30 mM PHENYLTHEPAZYRONE AND EXTRACTED INTO DCM. GLC ANALYSIS SUGGESTED THAT THE SIGNALS CORRESPOND TO LIQUID CHROMATOGRAPHY, AND THE MONOSACCHARIDE CONTENT WAS DETERMINED BY USING AN EXTERNAL CALIBRATION PROFILE AND AN INTERNAL TALOSE STANDARD.
alyzed with a FACScan flow cytometer (Beckton Dickinson). The net mean fluorescence intensity (MFI) was calculated by subtracting the value obtained in parallel with chimpzee E559 or guinea pig preimmune serum. The specificity of E2 binding to CD81 on human cells was confirmed as described previously (44) by competing E2 binding to human cells with soluble human CD81 LEL, which was purified as described previously (42) and incubated at a concentration of 50 μg/ml with E2 prior to incubation with MOLT-4 cells.

NOB assay. Mouse and guinea pig sera were tested for their ability to inhibit the binding of E2 protein to human target cells as previously described (25, 46). Briefly, NOB titers were determined by incubation of MOLT-4 cells with a nonsaturating concentration of biotinylated I-E2715 protein (1.5 μg/ml), which was preincubated with a test serum at different dilutions. Following incubation of the cells with a streptavidin-phycoerythrin conjugate (Southern Biotechnology Associates) at 2.5 μg/ml, E2 binding was measured with a FACScan. NOB titers correspond to the reciprocal values of serum dilutions which inhibit 50% of binding.

RESULTS

I-E2 but not S-E2 binds human target cells and elicits NOB antibodies following immunization. The E2 protein is processed from the HCV polyprotein, leading to a polypeptide backbone of 363 residues, spanning residues 384 to 746 (31). aa 716 to 746 serve as a membrane anchor, and their deletion can lead to secretion of the E2 protein when expressed in mammalian cells (34, 48). We previously described stably transfected CHO cell lines expressing E2, targeted to the ER via a TPA-derived leader sequence fused to its N terminus and carboxy-terminally truncated at residues 661 (E2661) or 715 (E2715). Both lines secrete a fraction of the E2 protein and retain part of it in the ER (49). Although E2661 is secreted from CHO transfectants with more efficiency than are longer truncated versions, we first aimed to purify and analyze the largest secreted E2 protein possible, and we previously reported the purification and binding to human target cells of E2715 (46). This E2 protein had been affinity purified from culture supernatants with MAb 5ES/H7 raised against the HeLa intracellular E1-E2 heterodimer, and we obtained E2 only in extremely small quantities. The low yield achieved with a conformational MAb used for purification led us to suspect that we had actually captured either a minor well-folded fraction or an intracellular fraction that had been released into the supernatant by occasional cell lysis. We then purified both the supernatant fraction (S-E2715) and the intracellular fraction (I-E2715) from the same line without the use of E2-specific antibodies. In Western blots, S-E2715 appeared as a broad band of about 74 kDa whereas I-E2715 appeared as a sharper band of about 60 kDa (Fig. 1A), indicating extensive usage of the 11 N-linked glycosylation sites within E2.

The E2 protein is an ideal vaccine candidate for the generation of antibodies that inhibit the binding of viruses to target cells. This antibody subset can be estimated in vitro by the NOB assay. To test the quality of different E2 antigens, we used S-E2715 and I-E2715 for immunization studies in guinea pigs. Both fractions raised high antibody titers as measured by ELISA, but only the internal fraction raised NOB antibodies (Fig. 1B and C).

We then measured the binding of the different forms of recombinant E2715 to CD81 and also included recombinant E2661 in these studies. For both truncated forms, I-E2 binding to target cells was saturable and was detected at concentrations as low as 0.1 μg/ml. Moreover, addition of purified recombinant human CD81 LEL blocked this binding completely, demonstrating the specificity of the interaction (Fig. 2A). By contrast, S-E2 bound weakly to cells and did not reach saturation at the maximum concentration used. As previously described, cell-bound E2 was detected using anti-E2 antisera raised in a chimpanzee immunized with intracellular E1-E2 heterodimer (46). We considered the possibility that the observed difference in binding was due to a decreased ability of this antiserum to recognize the complex glycosylated S-E2. We therefore repeated the experiments using antisera raised in guinea pigs against I-E2715 or S-E2715. Both antisera confirmed our finding that only the internal but not the secreted fractions of truncated E2 bind efficiently to CD81 (Fig. 2B and C).

Internal E2 monomers but not dimers or trimers bind efficiently to human cells. The recombinant E2 protein expressed in mammalian cells tends to aggregate, and these aggregates are stabilized by disulfide bonds. Such multimers of the HCV envelope are thought to be dead-end products (11, 34). We investigated whether the presence of oligomerized E2 protein in our preparations influences their ability to bind CD81. We separated forms of I-E2715 and S-E2715 with different molecular weights by gel filtration, through which we were able to purify monomers, dimers, and trimers of each. Both E2 forms display very similar gel filtration profiles, indicating that in both cases about 60% of the unfractionated material is monomeric (Fig. 3A). Only the monomeric fraction of I-E2715 bound efficiently to cellular targets, while the dimeric and trimeric fractions bound poorly. By contrast, neither monomers, dimers, nor trimers of S-E2715 bound CD81 efficiently. CD81 LEL blocks the binding of monomeric I-E2715 and S-E2715 completely, demonstrating the specificity of the interaction (Fig. 3B). Thus, aggregated recombinant E2715 fractions have an impaired capacity to present the conformational binding epitopes.

Sugar moieties are not necessary for E2 binding to human cells. Because the E2 protein elicited NOB antibodies upon immunization and bound CD81 only when core glycosylated but not when complex glycosylated, we tested whether core glycosylation was required for these activities. To this end, we performed binding studies using deglycosylated E2. We di-
gested I-E2_{715} with α-mannosidase or with endo H and analyzed the products for the presence of monosaccharides and for their binding activity. α-Mannosidase-digested E2 retains all GlcNAc residues compared to the undigested control, as well as, most probably, the β1→4 GlcNAc-linked and some α1→3 mannose-linked mannose residues, which are not efficiently cleaved by the enzyme (Table 1). Endo H digestion was complete, with approximately half of the GlcNAc residues cleaved off and only trace amounts of uncleaved mannose left. Importantly, the deglycosylated forms and the undigested controls were identical in their capacity to bind CD81 (Fig. 4). The enzymes alone have no binding activity (data not shown). Thus, core glycosylation is not necessary for E2 binding to CD81 and complex glycosylation is likely to mask the E2 binding epitope for its cellular receptor. This also may explain the inability of complex glycosylated S-E2_{715} to raise NOB antibodies after immunization. By treating S-E2 with peptide-N-glycosidase F (PNGase F), which removes complex sugars completely, we attempted to restore its binding activity. However, PNGase F-digested S-E2 formed high-molecular-weight aggregates, with the majority of the protein precipitating out of solution. The aggregates that remained in solution did not migrate into an SDS gel. This is presumably due to hydrophobic interactions following removal of all hydrophilic carbohydrates or due to conformational changes through the conversion of asparagine at the N-glycosylation site to aspartate. Therefore, it was...
Construction and in vitro analysis of ER-retained E2 DNA vaccines. Given the potential benefits of DNA vaccines over recombinant proteins (12), we assessed the ability of different E2 forms to stimulate humoral immunity if delivered in the form of a DNA vaccine. Using the DNA vaccination vector pAC, we constructed five E2-encoding plasmids (Fig. 5). (i) pAC-E2715 corresponds to the construct used for E2715 expression in CHO cells in that it encodes the same C-terminally truncated E2, directed into the ER by a TPA-leader sequence fused to its N terminus (aa 384), and driven by the human cytomegalovirus promoter. It was the basis for the other constructs, which all have the same N terminus and were made by modifying the C terminus of E2715. (ii and iii) pAC-E2 746 (ii) and pAC-E2 809 (iii) encode two naturally occurring membrane-anchored E2 species differing in their C termini (aa 746 and 809, respectively). The larger product contains a small highly hydrophobic region from aa 747 to 809, known as p7. Both forms are retained in the ER (31, 36, 48). Because the cellular localization of purified E2 antigen is critical, we assumed that ER retention of E2 protein expressed by DNA vaccines would favor the induction of NOB antibodies. (iv and v) Based on the same rationale, we additionally constructed pAC-E2715DEL (iv) by adding to the C-terminal lysine (aa 715) the three amino acids DEL to obtain the canonical signal for ER retention of luminal proteins, the amino acid motif KDEL (38), and pAC-E2730KK (v) by fusing to the C terminus of the first transmembrane-spanning domain of E2 (aa 730) the cytoplasmic tail of the adenovirus E3/19K protein, which confers ER retention and retrieval to transmembrane proteins (40, 50). The latter was constructed because despite the convincing in vitro data indicating its retention in the ER, full-length E2 has been reported to be present on the plasma membrane of hepatocytes in transgenic mice (26).

We next compared biochemical properties of E2 expressed in CHO cells stably transfected with our five DNA vaccination constructs. We were not able to detect an E2730KK protein, suggesting rapid degradation possibly due to incorrect folding. The other forms of E2 could be detected by Western blotting, and, as expected, all four are endo H sensitive, indicating an ER localization (Fig. 6). The proteins expressed from pAC-E2715DEL (E2 DEL) by adding to the C-terminal lysine (aa 715) the three amino acids DEL to obtain the canonical signal for ER retention of luminal proteins, the amino acid motif KDEL (38), and pAC-E2730KK (E2 KK) by fusing to the C terminus of the first transmembrane-spanning domain of E2 (aa 730) the cytoplasmic tail of the adenovirus E3/19K protein, which confers ER retention and retrieval to transmembrane proteins (40, 50). The latter was constructed because despite the convincing in vitro data indicating its retention in the ER, full-length E2 has been reported to be present on the plasma membrane of hepatocytes in transgenic mice (26).

* Assessed on pooled sera (eight mice per group) and expressed as the reciprocal values of serum dilutions.

** Mean values of individual NOB-positive sera (the number of NOB-positive sera per group of eight mice is given in parentheses).

The quality of recombinant E2 protein was assessed by two means: (i) the capacity to bind its putative receptor CD81 on human target cells and (ii) the capacity to elicit antibodies, in particular those that inhibit receptor binding (NOB antibodies). We show that CHO cell-expressed truncated E2 protein, when derived from the core glycosylated intracellular fraction (I-E2) but not from the complex glycosylated secreted fraction (S-E2), binds with high efficiency to human cells and elicits NOB antibodies in guinea pigs. We also show that carbohydrate moieties are not necessary for I-E2 binding to cellular targets and that only the monomeric fraction binds efficiently compared to multimers. Moreover, comparing recombinant I-E2 protein to several E2-encoding DNA vaccines in mice, we found that for both quantity and quality of the antibody response, protein immunization is superior to DNA. Based on these results, we propose that, for the induction of antibody responses, the E2 antigen needed in a future HCV vaccine is a recombinant, monomeric protein purified from the intracellular fraction.

In chimpanzees vaccinated with the E1-E2 heterodimer, high NOB antibody titers correlate with protection from infection with an homologous HCV isolate (46). However, when vaccinated chimpanzees were challenged with a heterologous virus, infection occurred in all animals but 9 of the 10 vaccinees did not develop chronic infection (M. Houghton and S. Abrigiani, unpublished data). Antisera from animals immunized with recombinant E1-E2 derived from the HCV-1 strain contained high titers of anti-E2 antibodies that were able to block CD81 binding of recombinant E2 derived not only from HCV subtype 1a but also from subtype 1b. By contrast, anti-E1 antibodies did not block the binding of E1-E2 to human cells. Together, immunization experiments in chimpanzees indicate that a vaccine based on HCV envelope proteins is able to prevent at least chronic HCV infection and that in the E1-E2 heterodimer, it is E2 that can generate antibodies capable of blocking virus binding to target cells. Thus, although sterilizing immunity was not achieved following challenge with heterologous virus, the prevention of chronic infection still holds promise, given that acute HCV infections are often asymptomatic and clinically inconsequential.

In an effort to produce recombinant HCV E2 in CHO cells, we originally focused on S-E2$_{715}$ whose purification is easier to scale up than is that of the intracellular fraction. Although we found that a supernatant fraction of E2 obtained by affinity chromatography binds human cells (46), we realized that our culture supernatant contained only a minor fraction of biologically active (in our binding assay) E2 protein. In an attempt to define the optimal forms of E2 for binding CD81, we assessed intracellular or secreted fractions of different truncated E2 proteins expressed in CHO cells. We found that both I-E2$_{661}$ and I-E2$_{715}$ bind substantially better to CD81 than do S-E2$_{661}$ and S-E2$_{715}$. It was found previously that S-E2$_{661}$ binds well to CD81 (18). However, the same authors recently reviewed this finding and reported that I-E2$_{661}$ binds CD81 with higher efficacy than does S-E2$_{661}$ (19). Our results not only confirm this finding but also give a functional correlate to the superior binding of I-E2 to CD81. We demonstrate, using S-E2$_{715}$ or I-E2$_{715}$ in immunization studies, that both fractions elicit high anti-E2 antibody titers as assessed by ELISA whereas only the I-E2 fraction raises NOB antibody titers. The finding that deglycosylated I-E2$_{715}$ binds CD81 on human cells as well as untreated I-E2$_{715}$ suggests that carbohydrates are not directly involved in the recognition of CD81. They could, however, play a role in the correct folding of E2 in the ER.

Given that robust virus cell entry assays and infection assays are not available, we do not know whether CD81 mediates HCV entry into cells. However, we have evidence that (i) CD81 is very inefficient in mediating internalization of bound ligands (42) and (ii) some hepatoma cell lines can bind recombinant envelope proteins in the absence of CD81 (data not shown), suggesting that hepatoma cells contain other molecules which interact with HCV and may mediate entry. Recently, the low-density lipoprotein receptor has been proposed as a possible HCV receptor (37) or, more generally, as a molecule exploited by members of the family Flaviviridae to enter human cells (1). However, until reliable infection assays are available, it will always be difficult to sort out the relative importance of candidate HCV receptors.

Little is known about the assembly and maturation of HCV. However, studies with recombinant proteins indicate that non-covalent heterodimers of E1 and E2 reside in the ER and are core glycosylated. They have been proposed as the prebudding form of the HCV envelope glycoprotein complex (11, 14).
When truncated forms of E2 pass through the Golgi and are secreted, they become complex glycosylated. Our results indicate that these modifications almost completely abolish the ability of E2 to bind to CD81 on human cells and to elicit NOB antibodies. Our view is that these complex sugars mask the binding site, most probably through steric or charge interference. Based on the results reported here, I-E2 probably mimics the binding site from further modifications. Although NOB titers do not necessarily correlate with total anti-E2 antibody titers in our experience with human sera (46), we cannot rule out that the low efficiency of NOB antibody production following DNA immunization is a direct consequence of the inability of the same DNA constructs to induce high anti-E2 antibody titers in general. DNA vaccines encoding intracellular proteins elicit poor antibody responses in comparison to secreted proteins (3). E2-encoding DNA vaccines therefore might be limited by their inherent inability to access and recognize epitopes on the cell surface. Vaccine 1999. Expression of noncovalent hepatitis C virus envelope glycoprotein complexes expressed by recombinant vaccinia and Sindbis viruses. J. Virol. 72:1294–1298.
