Received 10 October 2000/Accepted 24 December 2000

Viruses are suspected but usually unproven triggering factors in autoimmunity. One favored mechanism to explain the role of viruses in the genesis of autoimmunity is molecular mimicry. An immunoinflammatory blinding lesion called herpetic stromal keratitis (HSK) that follows ocular infection with herpes simplex virus (HSV) is suggested to result from a CD4 + T-cell response to a UL6 peptide of HSV that cross-reacts with a corneal autopeptide shared with the immunoglobulin G2a b (IgG2ab) isotype. The present report reevaluates the molecular mimicry hypothesis to explain HSK pathogenesis. Our results failed to reveal cross-reactivity between the UL6 and IgG2ab peptides or between peptide reactive T cells and HSV antigens. More importantly, animals infected with HSV failed to develop responses that reacted with either peptide, and infection with a recombinant vaccinia UL6 vector failed to cause HSK, in spite of generating UL6 reactivity. Other lines of evidence also failed to support the molecular mimicry hypothesis, such as the failure to affect HSK severity upon tolerization of susceptible BALB/c and B-cell-deficient mice with IgG2ab or UL6 peptides. An additional study system revealed that HSK could be induced in mouse strains, such as the OT2 × RAG1−/− mice (T-cell receptor transgenic recognizing OVA323–339) that were unable to produce CD4 + T-cell responses to any detectable HSV antigens. Our results cast doubt on the molecular mimicry hypothesis as an explanation for the pathogenesis of HSK and indicate that if autoimmunity is involved its likely proceed via a bystander activation mechanism.

That autoimmune diseases result from virus infection is an attractive hypothesis, but it has yet to be proven, at least for any human autoimmune syndrome (39). However, several animal models clearly link viruses and autoimmunity (11, 19, 25, 38, 40), although the mechanisms by which viruses trigger autoreactivity remain uncertain. The explanations for this include molecular mimicry and bystander activation (12, 39). The latter represents a complex which could include the release of normally sequestered antigens from damaged cells that now become immunogenic, alteration of host protein structure (27), and the subversion of host cells, causing proinflammatory mediator production or the synthesis of abnormal products such as autoantibodies (39). The more simple and perhaps most appealing idea to explain the genesis of virus-induced autoimmunity is molecular mimicry (19). This suggests that causative viruses express epitopes that cross-react with a host protein and that the initial immune response to viruses carries over to include anti-host reactivity (40). Proving unequivocally the molecular mimicry hypothesis in any model has been difficult (39).

One model advocated to support the molecular mimicry hypothesis is a blinding inflammatory reaction in the cornea set off by infection with herpes simplex virus (HSV). This lesion, termed herpetic stromal keratitis (HSK), is orchestrated by CD4 + T cells that are suggested to recognize autoantigens in the cornea (31, 36). One such autoantigen may be a 16 amino acid peptide shared by the immunoglobulin G2a b (IgG2ab) isotype (2). A peptide of almost identical amino acid sequence is found in the UL6 protein of HSV, and this has been advocated as the molecular mimic which elicits the HSK syndrome (41). Supporting the corneal autoantigen hypothesis is the observation that mice such as C57BL/6 (B6) and CB.17, which express the Ig2ab isotype and so are immunologically tolerant to the autoantigen, are highly resistant to HSK development (2, 21, 35). In addition, viral mutants that lack the mimicking peptide fail to induce HSK in susceptible mouse strains and lesions can be adoptively transferred to virus-infected nude mice with UL6 and IgG2a immune T cells (2, 41). Accordingly, the case for HSK representing an autoimmune reaction set off by a virus that acts as a molecular mimic appears persuasive.

In the present report, we readdress the role of autoimmunity and molecular mimicry between IgG2a and UL6 peptides in HSK pathogenesis by using a mouse model involving different mouse strains on the same genetic background as used in the previous reports and a strain of HSV type 1 (HSV-1) (strain RE) usually used for the induction of HSK lesions. Mouse strains used in the study included susceptible BALB/c (B/c) mice, resistant B6 mice, and B6 μ-chain knockout (Bk/o) mice. The latter do not produce immunoglobulin (Ig) and therefore would lack tolerance to the corneal autoantigen shared with the IgG2ab isotype. Several observations failed to support the molecular mimicry hypothesis. First, analysis of in vivo delayed-type hypersensitivity (DTH) reactions and in vitro T-cell
responses of draining lymph node and splenocytes revealed none of the expected cross-reactivities. Accordingly, mice ocularly infected with HSV failed to generate demonstrable in vivo and in vitro responses to either the UL6 or IgG2ab peptides. Second, although infection with recombinant vaccinia virus expressing the UL6 protein induced T cells that reacted with the UL6 peptide, neither cross-reactivity with the IgG2ab peptide nor cross-reactivity with HSV could be demonstrated. Moreover, mice immunized with either UL6 or IgG2ab peptides elicited T cells that reacted only with homologous peptides. Third, attempts to change the susceptibility of B/c or Bk/o mice by tolerizing them to the UL6 or IgG2ab peptides prior to HSV infection failed to significantly affect their HSK susceptibility status. Fourth, adoptive transfer of HSV immune CD4+ T cells to SCID mice later infected with replication-defective mutants, which were either UL6 positive or negative, both failed to yield HSK. Finally, we demonstrated that OT2 × RAG1−/− (OT2xRAG1−/−) mice, which are T cell transgenic to recognize an OVA peptide, still develop HSK; yet such mice failed to recognize any HSV antigens. Although our results cannot exclude autoreactivity as being involved in the pathogenesis of HSK, taken together, they provide no support that the UL6 protein or any other protein of HSV provides a molecular mimic which induced molecular mimicry. Rather, our results indicate that HSV represents an immunoinflammatory reaction which, if in part autoimmune, involves a bystander activation mechanism.

MATERIALS AND METHODS

Mice. B/c mice and B6 mice (4 to 6 weeks old) were purchased from Harlan Sprague-Dawley (Indianapolis, Ind.). B-cell-deficient mice (Bk/o, H-2b-background), made by targeted disruption of the membrane exon of the Ig μ-chain...
gene (13) were kindly provided by H. W. Virgin (Washington University School of Medicine, St. Louis, Mo.). OT2xRAG1<sup>−/−</sup> mice were kindly provided by J. Kapp (Emory University, Atlanta, Ga.) (22). BALB/c SCID mice (Taconic Farms, Germantown, N.Y.) were bred in the specific-pathogen-free facility. All manipulations involving the SCID and RAG1<sup>−/−</sup> mice were conducted in a laminar flow hood. To prevent bacterial superinfections, all SCID and RAG1<sup>−/−</sup> mice received prophylactic treatment of a Sulfatrim pediatric suspension (Barrett Farms, Germantown, N.Y.) were bred in the specific-pathogen-free facility. All manipulations involving the SCID and RAG1<sup>−/−</sup> mice were conducted in a laminar flow hood. To prevent bacterial superinfections, all SCID and RAG1<sup>−/−</sup> mice received prophylactic treatment of a Sulfatrim pediatric suspension (Barrett Farms, Germantown, N.Y.).

Virus and reagents. The HSV-1 RE and HSV-1 KO strains were propagated and titrated on monolayers of Vero cells (ATCC CCL81) by using standard protocols (30). All virus stocks were separated into aliquots and stored at −80°C. Vaccinia virus expressing UL6 was kindly provided by A. H. Patel (Glasgow University, Glasgow, United Kingdom). The ICPS<sup>−/−</sup> HSV-1 KO mutant was kindly provided by D. Knipe (Harvard University, Boston, Mass.), and the ICP<sup>−/−</sup> HSV-1 KO mutant was from J. C. Glorioso (University of Pittsburgh, Pittsburgh, Pa.). UL6 (299–314), IgG2a (292–308), and hemagglutinin (HA) peptides were synthesized by Genemed Synthesis, Inc., South San Francisco, Pittsburgh, Pa.). UL6 (299–314), IgG2a (292–308), and hemagglutinin (HA) peptides were synthesized by Genemed Synthesis, Inc., South San Francisco, Pittsburgh, Pa.).

<sup>a</sup> Mice (n = 6) were immunized subcutaneously at the base of neck with 100 μg of peptide in CFA or else infected with HSV-1 RE on scarified corneas (Bic, 5 × 10<sup>9</sup> PFU; B6, 10<sup>7</sup> PFU). At days 9 to 15 postimmunization and days 15 to 18 post-HSV infection, splenocytes or cervical and submandibular DLN cells (2 × 10<sup>6</sup> cells/ml) were in vitro stimulated with a 1.5 MOI of UV-irradiated HSV-1 (UV-HSV) KOS, ConA (5 μg/10<sup>6</sup> cells/ml), or peptides (5 μg/ml). Uninfected splenocytes were used as negative controls. Culture supernatants from each group were collected and analyzed for cytokine production by ELISA assay as described in Materials and Methods. The data represent the means ± the standard deviations from two experiments, each of which included three individual mice. The limit of detection of the ELISA was 0.3 ng/ml. Statistically significant differences between stimulated groups (P < 0.05) are indicated by an asterisk.

Analysis of viral expression of UL6 protein. HEP-2 cells were infected with the indicated viruses at a multiplicity of infection (MOI) of 200 or were mock infected. At 12 h postinfection, total cell extracts were prepared, and proteins were resolved by sodium dodecyl sulfate-polyacrylamide gel electrophoresis in a 9% DATD (N, N'-diallyltartardiamide)-cross-linked sodium dodecyl sulfate-gel, transferred by electroblotting, and processed for immunoblotting using rabbit polyclonal anti-UL6 antibody (1:500 dilution) kindly provided by Joel Baines (33) and secondary antibody, followed by visualization as described previously (29).

DTH. At day 10 post-virus infection on scarified corneas of mice or with peptide immunization in complete Freund adjuvant (CFA), test antigens in 20 μl of phosphate-buffered saline (PBS) were injected in the left ear pinna of anesthetized mice, and PBS diluent (peptide-specific DTH reaction) or Vero cell extract (HSV-specific DTH reaction) was injected in the right ear, respectively. Ear thickness was measured 48 h postinjection with a screw gauge meter (Odident-weight Pharm Bi, Schleurheim, Germany) as described elsewhere (14). The test antigens used were 20 μl of UV-inactivated HSV-1 KOS (10<sup>9</sup> PFU prior to UV inactivation) or 10 μg of peptide per ml. The mean increase between the thickness of the left and right ear was calculated and is expressed in 10<sup>−2</sup> mm.

Lymphoproliferation assay. To test antigen-specific T-cell responses, individual spleens and cervical and mandibular lymph nodes were used as responders for lymphoproliferation assays stimulated with enriched dendritic-cell populations obtained by the method of Nair et al. (18). Briefly, these responders were restimulated in vitro with irradiated syngeneic dendritic cells infected with HSV UV-1 KO (MOI = 5.0) or pulsed with peptides at various concentrations or with irradiated naive dendritic cells and then incubated for 4 days at 37°C for peptide-stimulation or for 5 days for HSV-1 stimulation. At 18 h before harvesting, [3H]thymidine (1.0 μCi/well) was added to all culture wells, and the plates were read using a β-scintillation counter (Trace 96; Inotech, Lansing, Mich.). The results were expressed as mean counts per minute (cpm) ± the standard deviation.

Quantification of IFN-γ production by ELISA. To assay for gamma interferon (IFN-γ) production, 2 × 10<sup>5</sup> splenocytes per ml were stimulated in vitro with 5 μg of peptide or UV-inactivated virus-pulsed irradiated syngeneic antigen-presenting cells per ml. Supernatants were collected at 48 h for concanavalin A (ConA) stimulation (5 μg/ml), at 72 h for peptide stimulation (5 μg/ml), or at 96 h for UV-inactivated HSV-1 (MOI = 5.0) or vaccinia virus (MOI = 5.0) stimulation and then screened for the presence of IFN-γ by enzyme-linked immunosorbent assay (ELISA) as described previously (5).

Histopathology and immunohistochemical staining. Eyes were enucleated and fixed in 10% buffered neutral formalin and embedded in paraffin as described previously (35). Sections (5 μm thick) were cut and stained with hematoxylin and eosin. For immunohistochemistry, eyes were frozen in optimum cutting temperature (OCT) compound (Miles, Elkart, Ind.). The sections (5 μm thick) were cut,
air dried, and fixed in cold acetone for 5 min. The sections were then blocked with heat-inactivated rabbit serum (Sigma) and stained for the presence of HSV antigens by the use of rabbit anti-HSV antiserum (Dako Corp., Carpinteria, Calif.), which was followed by treatment with biotinylated anti-rabbit antibody (1/20 dilution; Biogenex, San Ramon, Calif.). Alternatively, sections were stained with biotinylated anti-CD4 or anti-KJ1-26.1 antibody (biotinylated anti-OVA-TCR, a kind gift from Jerold Woodward, University of Kentucky, Lexington, Ky.). Sections were treated with horseradish peroxidase-conjugated streptavidin (1/1,000 dilution; Jackson Immunoresearch Laboratories, Inc.) and 3,3′-diaminobenzidine substrate (Biogenex, San Ramon, Calif.) and then counterstained with hematoxylin. For OVA-TCR (KJ1-26.1) staining, sections were pretreated with a tyramide signal amplification kit (TSA Indirect; Dupont NEN, Boston, Mass.) before treatment with diaminobenzidine.

Flow cytometry. Cervical lymph node cells were analyzed for the cell surface expression of activation markers. Viable cells were blocked with heat-inactivated fetal bovine serum and washed with flow cytometry buffer (1× PBS with 1% bovine serum albumin and 0.05% sodium azide). Cells were double stained with anti-CD4-FITC (Pharmingen) and anti-CD44-PE (Pharmingen) or with anti-CD62L-PE (Pharmingen) and anti-CD45RB-RPE (Calbiochem). Events were recorded with FACSCALIBUR (Becton Dickson, San Jose, Calif.) and analyzed using Cellquest 3.0 version (Becton Dickson).

Statistical analysis. Wherever specified, the data obtained were analyzed for statistical significance by using the Student’s t test.

RESULTS

Analyses of cross-reactivity of Ig peptide and UL6 peptide of HSV in B/c and B6 mice. Previous reports indicate that HSK in a susceptible mouse strain represents an immune response against a peptide derived from the UL6 protein of HSV that cross-reacts with a corneal autoantigen that forms part of the IgG2a (amino acids 292 to 308) Ig isotype encoded by the IgHb locus (2). This latter peptide is referred to as G2a. If the UL6 peptide acts as a molecular mimic of G2a and is indeed involved in the pathogenesis, then HSV ocular infection would be expected to induce T-cell responses in recipient animals that react with both the UL6 and the G2a peptides. To test these ideas, groups of susceptible B/c and resistant B6 mice were infected on scarified corneas with HSV or were immunized systemically with either the UL6 or G2a peptides emulsified in CFA. The resultant pattern of reactivity was measured. By 10 days postinfection HSV-infected B/c mice showed
signs of HSK which gradually increased in severity over the next 2 weeks (data not shown). In contrast, under the same infection conditions B6 mice showed none or extremely mild signs of HSK (data not shown). However, with regard to antigen-specific immune reactivity, several points are recorded in Fig. 1 and Table 1. First, HSV infection of both mouse strains resulted in T-cell responses reactive to virus detectable in vivo by the DTH reaction (Fig. 1A and B) or in vitro in lymphoid tissues by specific lymphoproliferation (Fig. 1C and D) or cytokine release (Table 1). However, neither B/c nor B6 mice showed detectable cross-reactivity against either the UL6 or G2a peptides. It was evident, nevertheless, that both the UL6 and G2a peptides were immunogenic in B/c mice, but the responses detected were neither mutually cross-reactive nor reactive in vitro with HSV-1. Interestingly, the UL6 peptide was not as immunogenic as the G2a peptide in the B/c mice strain. Furthermore, as expected, the G2a peptide was not immunogenic in the B6 strain in which it is a self-peptide.

These results fail to support molecular mimicry and indicate that the UL6 protein of HSV fails to induce detectable UL6 peptide-specific responses in lymphoid tissue following ocular infection. However, to further examine a possible role of UL6 in HSK, B/c mice were ocularly infected with a recombinant vaccinia virus expressing the UL6 protein (kindly provided by A. H. Patel). This infection failed to cause lesions typical of HSK (data not shown), but analysis of DLN at 14 days postinfection revealed UL6 peptide-specific T cells detectable by proliferation (Fig. 2A) or IFN-γ cytokine release assay (Fig. 2B). Nevertheless, the same population failed to react with the G2a peptide or to stimulation with HSV antigen. Taken together, the data indicate that the UL6 protein in HSV infections is not a strong immunogen. Immune reactivity against

FIG. 4. Infection with replication-defective HSV (UL6 positive or negative) fails to induce HSK in SCID mice reconstituted with HSV immune T cells. SCID mice (n = 5/group) were infected with ICP4−/−, ICP8−/−, and HSV-1 KOS (5 × 10⁵ PFU) on scarified corneas at days 0, 2, and 4. At day 1 postinfection, SCID mice were reconstituted with 10⁷ HSV immune splenocytes in a 400-μl volume of 1× PBS given i.v. The data represents the results from one of two independent experiments with similar results. (A) Mean clinical scores of SCID mice at days 7, 9, 11, and 12 postinfection. Mice were scored by using a slit-lamp microscope as described in Materials and Methods. (B and C) Mice were terminated at day 13 postinfection, and cervical and submandibular DLN cells were used as responders in an HSV-specific lymphoproliferation assay (C) or were stained for activation markers CD62L, CD45 RB, and CD44 by flow cytometry assay (B) as described in Materials and Methods. The percentage of cell surface expression of activation markers under marker M2 is indicated in the histograms. The data indicate the presence of activated HSV-specific CD4⁺ T cells in all of the wild-type and mutant virus-infected reconstituted SCID mice groups irrespective of the development of HSK lesions shown in panel A.
UL6, however, can be detected only under ideal circumstances, such as when administered with adjuvant or in the form of vaccinia virus expressing UL6 protein.

A further experiment to test the role of a peptide derived from the UL6 protein in the pathogenesis of HSK, was to analyze the susceptibility of SCID mice infected with HSV or mutant viruses and reconstituted with CD4\(^+\) T cells reactive to HSV. This reconstitution model results in HSK, provided the SCID mice are infected with wild-type HSV (16). However, when reconstituted SCID mice were repeatedly infected at days 0, 2, and 4 with either ICP4\(^-\) mutant d120, which expressed little if any UL6, or an ICP8\(^-\) mutant (which expressed UL6 at levels about one-third that of the wild-type virus) (Fig. 3), neither infection resulted in the expression of HSK (Fig. 4A). However, the infection procedure was assumed to be immunogenic, since the recipient mice developed lymphadenopathy, had an increased number of activated cells in the draining lymph nodes (DLN) (Fig. 4B), and showed enhanced HSV-specific lymphoproliferation responses compared to uninfected reconstituted SCID mice (Fig. 4C) in samples tested at day 11 postinfection.

**Role of the Igh-1b locus in affecting susceptibility to HSK.**

The autoimmune hypothesis explaining the pathogenesis of HSK finds support from the observation that the susceptible mouse strains develop CD4\(^+\) T cells reactive to the G2a peptide expressed in the damaged corneal stroma during HSK (2). Resistant strains such as CB17 and B6 do not recognize the G2a peptide, since in these strains the peptide is a self-component. Our data support the observation that HSV resistant B6 mice fail to respond to G2a peptide upon immunization in CFA (Fig. 5A). In contrast, mice of the B6 background that lack Ig expression because of an Ig \(\mu\)-chain knockout did respond upon immunization with the G2a peptide (Fig. 5A). Furthermore, Bk/o mice were far more susceptible to ocular infection with HSV (Fig. 6). At doses of virus well tolerated by B6 mice, most Bk/o animals succumbed to viral encephalitis. At lower, nonlethal doses of HSV infection, most Bk/o mice expressed HSK, whereas the same virus dose failed to induce lesions in B6 mice. The observation of greater susceptibility combined with reactivity to the G2a peptide could appear as supportive of autoimmunity pathogenesis in HSK. However, the data in Fig. 5B cast doubt as to any role for the G2a peptide in Bk/o mice. Accordingly, following HSV infection of such mice, the animals failed to develop demonstrable reactivity in the DLN to the G2a peptide nor, in fact, to the UL6 peptide. Nevertheless, the mice did develop reactivity to HSV.

To further test the putative role of the G2a peptide as the autoantigen recognized by CD4\(^+\) T cells in HSV-susceptible mice, the effects of tolerization against the peptide on the subsequent susceptibility to ocular infection was investigated.
Should the G2a peptide be a major target during HSK, tolerization was expected to diminish susceptibility to HSK, as was indicated to occur in susceptible CAL.20 mice tolerized with the G2ab protein (2). In our experiments, both B/c and Bk/o mice were tolerized by exposure to high amounts of the soluble peptide, as described by others (2, 41). Mice were judged to be tolerant based upon their subsequent response to immunization with the G2a or UL6 peptide in CFA. As shown in Fig. 7, tolerized mice had markedly diminished peptide-specific proliferation and cytokine responses compared to controls. Despite the apparent tolerization of both B/c and Bk/o mice, both failed to become more resistant to HSK compared to control animals. These data cast doubt regarding the contribution of the G2a peptide, at least in HSK-susceptible B/c and B6 Bk/o mice, to HSK pathogenesis.

An explanation for the heightened susceptibility of Bk/o mice to HSK. As indicated previously, Bk/o mice of the same genetic background as B6 mice, yet lacking B cells and the ability to produce antibody, were highly susceptible to ocular infection with HSV. Although viral clearance with respect to HSV infection is usually considered principally carried out by T-cell-mediated immunity (21), the inability to generate antibody may result in a more prolonged infection of the cornea. This was in fact the case, as shown in Fig. 8. The duration of detectable virus in ocular swabs was at least 4 days longer in Bk/o mice than in B6 mice. This prolonged presence of virus...
could bring into operation an additional mechanism of pathogenesis referred to as bystander activation (6, 7). Thus, as observed previously, T-cell-transgenic B/c mice backcrossed to SCID or RAG still develop HSK, even though they are unable to immunologically recognize HSV antigens (6, 7, 8). Support for the bystander mechanism to explain the HSK pathogenesis is shown in Fig. 8. The results show HSK following HSV infection of mice on a B6 background that were T cell transgenic, with their CD4^+ T cells recognizing the OVA 323–339 peptide. Such OT2 mice were backcrossed to RAG^−/− and so were incapable of producing Ig and generated negative or minimal T-cell responses to antigens other than the OVA peptide (22). Upon HSV infection of scarified corneas, the animals developed typical HSK before dying of encephalitis at ca. day 13 postinfection. Animals failed to express detectable HSV-specific immune responses (Table 2) even if animals were repeatedly immunized with UV-inactivated HSV (data not shown). The presence of viral antigens in the corneal stroma of such mice evident at the site of inflammation likely provides the stimulus for bystander activation of T cells (Fig. 9B), resulting in HSK (Fig. 9A, C, and D). Since the OT2xRAG1^−/− mice failed to develop detectable immune responses to HSV and yet still developed HSK, as was also observed in other strain combinations (7, 8), these data fail to support a role for any HSV protein as providing a molecular mimic of a corneal autoantigen involved in HSK.

DISCUSSION

Viruses are suspected as triggering agents in several autoimmune lesions with several mechanisms likely involved (39). A favored hypothesis is that viruses contain epitopes that cross-react with host proteins and that the immunity induced reacts both to virus and to self. This molecular mimicry hypothesis arouses enthusiasm (19), but it has been difficult to prove, especially in natural of autoimmune diseases. One animal disease model that supports molecular mimicry is HSK, a blinding immunoinflammatory reaction of the cornea caused...
by HSV infection (31, 36). Molecular mimicry in HSK is suggested to occur between the HSV-encoded protein UL6 and a corneal autoantigen that also forms part of the IgG2a isotype of Ig (2, 41). The present report, however, raises doubt that molecular mimicry, at least with regard to the UL6 protein, explains the pathogenesis of HSK. Accordingly, if a peptide derived from an HSV protein was principally involved in driving an inflammatory reaction, either virus induced or autoreactive, it would likely be strongly immunogenic and induce a readily detectable immune response in infected animals. In our studies, we failed to detect UL6 peptide-specific T-cell responses in either the DLN or splenocytes of HSV-infected animals. Animals could process and respond to the UL6 peptide, however, since animals ocularly infected with a recombinant vaccinia virus vector that expressed the UL6 protein generated UL6 peptide-specific T cells. Also, contrary to the molecular mimicry idea, we were unable to detect cross-reactivity between the UL6 and G2a peptides when DLN cells from peptide-immunized mice were analyzed for lymphoproliferation or cytokine-producing responses in vitro. Additionally, tolerization of susceptible recipients to either UL6 or G2a peptides had no demonstrable effect on the nature of their HSK lesions, and when SCID mice, reconstituted with HSV immune CD4\(^+\) T cells, were infected with UL6\(^{+}\) or UL6\(^{-}\) HSV mutants, neither type of infection resulted in HSK. Finally, HSK could still be induced in OT2xRAG1\(^{-/-}\) mice that were unable to mount detectable immune responses against HSV antigens. Taken together, our results fail to support a role for molecular mimicry involving HSV proteins, and particularly UL6, in the pathogenesis of HSK. Although we cannot exclude autoimmune events as contrib-
uting to lesion expression, these would seem to involve mechanisms such as bystander activation rather than molecular mimicry.

Although it is likely that infectious agents are involved in the causation and expression of autoimmune diseases, it has been difficult to verify this notion, especially with human autoimmune diseases (39). The case for infectious agents as causes of some animal autoimmune diseases is stronger particularly for inflammatory demyelinating disorders. For example, both Theiler’s virus and murine corona virus appear able to cause autoreactive lesions in the central nervous system (4, 17, 34). In these examples, the mechanisms involved remain unresolved, but they are unlikely to involve molecular mimicry (4, 17, 34).

Another model, coxsackievirus myocarditis, it often assumed to be an autoimmune lesion resulting from molecular mimicry (12, 20), but since the virus persists (32) this model could

![Image](http://jvi.asm.org/content/3086/6/D3086FFIG9A.png)

**FIG. 9.** Viral antigen and CD4\(^+\) KJ1\(^+\) T cells in the corneal stroma of OT2xRAG1\(^{-/-}\) HSV ocularly infected mice. OT2xRAG1\(^{-/-}\) mice were infected with 2\( \times \)10\(^6\) PFU virus on scarified corneas. At days 10 to 13 postinfection, mice were sacrificed, and the eyes were snap-frozen in OCT compound. (A) Histopathology of infiltrating cells in the corneal stroma. (B) Immunohistochemistry for viral antigens in the corneal stroma (magnification, \(\times 200\)). (C and D) Immunohistochemistry for CD4\(^+\) cells (magnification, \(\times 400\)) (C) and for OVA\(_{323-339}\) TCR clonotypic antibody KJ1-26.1\(^+\) cells (magnification, \(\times 400\)) (D).
represent a chronic antiviral response rather than autoreactivity (9, 23). Similarly, coxsackievirus has been incriminated in insulin-dependent diabetes mellitus by a molecular mimicry mechanism (1). However, this notion has been questioned by others based on the development of diabetes in TCR-transgenic mice that involves islet antigens that differ from those implicated in molecular mimicry (10).

Molecular mimicry as an inciting mechanism for autoimmunity has been suggested for several additional rodent autoimmune-disease models, but in almost all cases the evidence is circumstantial or unconfirmed (39). The basis for the view that HSK is an autoreactive T-cell-mediated lesion is also largely circumstantial and derives mainly from the observation that lesions persist and may even progress in the apparent absence of viral antigens (31, 36). The best evidence that HSK could be an autoimmune lesion involving molecular mimicry came from an analysis of the susceptibility status of two congenic strains of mice differing only in the IgH locus (encoding the IgG2a isotype of Ig) (2, 41). In such studies, corneal extracts from susceptible affected mice could stimulate T-cell clones reactive with a 16-amino-acid peptide of IgG2a. Moreover, the G2a-specific T-cell clones could transfer disease to usually resistant HSV-infected athymic mice. In addition, susceptible CAL.20 mice became resistant if tolerized with the G2a peptide prior to infection. Subsequently, the molecular mimicry hypothesis was invoked since a peptide in the UL6 protein shared sequence similarity with G2a (41). In addition, lesions in susceptible mice were reported to occur only if animals were infected with UL6+ but not with UL6− HSV mutants. Taken together, such data make a strong case for molecular mimicry and autoimmune in HSK.

In the present report using slightly different mouse strains but with the same IgH locus disparities, we failed to confirm a role for a UL6 epitope in HSK. We have no explanation for our discordant results. We reasoned that, as is noted to occur with other models that involve molecular mimicry (19, 39), if the UL6 peptide is involved as a molecular mimic in HSK pathogenesis it should be a potent immunogen when the virus was used for infection. Our studies failed to demonstrate any UL6 peptide-specific responsiveness in mice infected with HSV, although weak though undetectable responses remain a possibility. In addition, T cells reactive with UL6, taken from peptide-immunized mice, neither reacted with HSV-infected cells (not shown) or indeed the G2a peptide. Furthermore, if the UL6 peptide, cross-reacting with G2a, accounts for the HSK lesions, one might have expected lesions to result from ocular infection with a recombinant vaccinia virus expressing UL6 protein (which induced UL6 peptide reactivity). This did not occur. Finally, we consistently failed to induce HSK in reconstituted SCID or nude (not shown) mice repeatedly in infection. Subsequently, the molecular mimicry hypothesis was invoked since a peptide in the UL6 protein shared sequence similarity with G2a (41). In addition, lesions in susceptible mice were reported to occur only if animals were infected with UL6+ but not with UL6− HSV mutants. Taken together, such data make a strong case for molecular mimicry and autoimmune in HSK.

In the present report using slightly different mouse strains but with the same IgH locus disparities, we failed to confirm a role for a UL6 epitope in HSK. We have no explanation for our discordant results. We reasoned that, as is noted to occur with other models that involve molecular mimicry (19, 39), if the UL6 peptide is involved as a molecular mimic in HSK pathogenesis it should be a potent immunogen when the virus was used for infection. Our studies failed to demonstrate any UL6 peptide-specific responsiveness in mice infected with HSV, although weak though undetectable responses remain a possibility.
