Received 7 March 2003/Accepted 14 July 2003

Insects exhibit effective immune system measures such as humoral and cellular responses against microbial infection (4). Insect immunity in antibacterial reactions has been the most extensively studied (7, 8, 13). On the other hand, little is known about insect immunity against viruses (16). *Bombyx mori* nucleopolyhedrovirus (BmNPV) is a most significant virus in the sericultural industry, often causing severe economic damages. The immune mechanisms of *B. mori* against this virus remain totally obscure.

The infection cycle of BmNPV is mediated by two phenotypically different viral particles: the occlusion-derived virus (ODV) and the budded virus (BV) (9). Oclusion bodies consisting of a crystalline matrix of polyhedron proteins contain ODV particles. When the occlusion bodies are ingested by *B. mori* larvae, they are dissolved by the alkaline gut juice. The enveloped virions are released and then initiate infection in the midgut columnar epithelial cells. In the case of *Autographa californica* multicapsid nucleopolyhedrovirus, it was shown that a proportion of the parental virus travels through the midgut epithelial layer, possibly utilizing the plasma membrane reticular system, and enters the hemocoel at the same time, infecting the hemocytes (3). In contrast to ODV, the BV particle consists of a single nucleocapsid surrounded by an envelope acquired as it buds from the plasma membrane of an infected cell and spreads beyond the midgut through the tracheae.

Studies on antiviral immunity in insects are still in their infancy, and defense mechanisms at an early stage of viral infection in the alimentary canal remain unknown. The aim of the present study was to determine whether *B. mori* contains proteins showing anti-BmNPV activity in the gut in order to obtain a clue as to the antiviral mechanisms involved in insect immunity.

A protein showing anti-BmNPV activity was purified through ammonium sulfate fractionation, gel filtration, and reverse-phase high-performance liquid-column chromatography (HPLC) (Fig. 1A). The protein was eluted with 49.5% acetonitrile–0.05% trifluoroacetic acid (TFA) by reverse-phase HPLC. The homogeneity of the antiviral peak fraction was examined both by matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) using a Voyager RP biospectrometry system (PerSeptive Biosystems) and by liquid chromatography-mass spectrometry (LC-MS) using a Series 1100 MSD (Hewlett-Packard). The results showed no contamination of this protein fraction (Fig. 1A, inset). The molecular mass of this protein was calculated to be 28,988 Da by MALDI-TOF MS and 28,978 Da by LC-MS. The protein showed strong antiviral activity against ODV of BmNPV (Fig. 1B). All fifth-instar larvae inoculated with ODV (22.5 ng/larva) showed strong antiviral activity against ODV of BmNPV (Fig. 1B). All fifth-instar larvae inoculated with ODV (22.5 ng/larva) treated with this protein (2.2 μg/larva) entered the pupal stage, although all control larvae inoculated with nontreated ODV died within 168 h postinfection (hpi) (data not shown).

A partial N-terminal amino acid sequence (NH$_2$–NGA NNOQYWLFTRRNQHQVITNGVNSI) of the protein was determined by using a 492cLc protein sequencer (PE Applied Biosystems). This sequence was identical to that of an expressed sequence tag (EST) clone. The complete nucleotide sequence of the protein was determined based on the EST clone designated mg809 (Fig. 2). The molecular mass of the deduced amino acid sequence was calculated to be 28,974 Da, coincident with the masses as measured by MALDI-TOF MS and LC-MS. A computer-aided homology search for the deduced amino acid sequence of this protein showed 56% homology with *Drosophila melanogaster* lipase (1) and 21% with human lipase (6) (Fig. 3A). The amino acid residues for the active site of the lipase family (GXSXG) (10), where X is any amino acid residue, were completely conserved. Thus, lipase activity was examined to confirm that the purified protein has biological activity consistent with a lipase. The results showed that the protein has lipase activity (Fig. 3B), suggesting that a lipase is involved in immune mechanisms against viral infection in the alimentary canal. This protein was therefore designated...
FIG. 1. Final HPLC purification profile and antiviral activity of Bmlipase-1. (A) Purification profile of Bmlipase-1. Bmlipase-1 was eluted with 49.5% acetonitrile–0.05% TFA by reverse-phase HPLC. The arrow indicates the Bmlipase-1 position. The inset shows the LC-MS spectrum with molecular mass of Bmlipase-1.

B. mori larvae of the Daizo race were reared on mulberry leaves, whereas larvae of the Tokai/H11003 Asahi race were fed an artificial diet (Nihonnosanko). The silkworms were maintained in the silkworm rearing room under controlled environmental conditions at 27°C. The digestive juice was collected from B. mori (Daizo race) larvae in an ice-cold tube by mild electric shock, and ammonium sulfate was added to give a 40% saturation. The precipitate was suspended in 40 mM phosphate buffer (pH 7.4) and treated with 50% n-butanol (final concentration) overnight at 4°C, and the lower aqueous layer was collected after centrifugation at 10,000 g for 30 min. Half-volume ice-cold acetone was added to this solution to precipitate proteins in the aqueous layer. The precipitated proteins were collected by centrifugation at 10,000 g for 30 min, dried, and dissolved in 40 mM phosphate buffer (pH 7.4). The solution equilibrated with the same buffer was applied to a Superdex 200 HR 10/30 column attached to a fast-performance liquid chromatography system (Pharmacia). Each fraction was tested for antiviral activity. Antiviral fractions were further purified through a reverse-phase column, Sephasil C8 SC 2.1/10, attached to a SMART system (Pharmacia) with a linear gradient of acetonitrile–0.05% TFA. (B) Antiviral activity against BmNPV-ODV. Infectivity was expressed as relative light units/10^9262 l of hemolymph. The data shown are means ± standard deviations of results from five experiments. The infectivity of BmNPV treated with 22.5 ng/larva. Luciferase activity was measured at 136 hpi. The antiviral activity was assayed using BmNPVp10luc, which contained a luciferase reporter gene driven by the p10 promoter (15). The recombinant BmNPV was a gift from Shuichiro Tomita from our institute. The virus expresses a luciferase reporter gene at 15 hpi. The infection and mortality levels were quantified in the Tokai × Asahi race. The ODV was purified by ultracentrifugation on sucrose gradient (14). The ODV (22.5 ng/larva) suspension was mixed with the purified protein (2.2 mg/larva) and dissolved in 40 mM phosphate buffer (pH 8.0). This mixture was incubated at 30°C for 1 h. Fifth-instar larvae just after ecdysis were orally inoculated with 5×10^7263 l of ODV mixture. Thirty larvae were used for each treatment. The hemolymph was collected at various hpi and assayed for luciferase activity. Ten microliters of hemolymph was added to 50 l of luciferase assay buffer (Promega), and luciferase activity was measured using a Luminocounter 700 (Microtech-Nition).

FIG. 2. Nucleotide and deduced amino acid sequences of Bmlipase-1 cDNA. The putative signal sequence of purified Bmlipase-1 is underlined. Boxed amino acid residues denote the active site of the lipase family (10). An asterisk shows the termination codon (TAA). The polyadenylation signal is double-underlined. B. mori EST database (Silkbase; http://www.ab.a.u-tokyo.ac.jp/silkbase/) was screened based on the N-terminal amino acid sequence of the purified protein. A clone (mg809) isolated from the midgut cDNA library showed homology with this protein. The nucleotide sequence of the mg809 clone, kindly provided by Kazuei Mita from our institute, was determined to lack the sequence of the 5′ region. Complete nucleotide sequence was obtained by a First Choice RLM-RACE kit (Ambion) using mRNA extracted from the midgut and purified by a Quick Prep mRNA kit (Amersham Pharmacia Biotech). The nucleotide sequence was determined by dye-terminator cycle sequencing using a DNA sequencer (ABI 373A).
Bmlipase-1. A Bmlipase-1 analogue cDNA was also cloned. The deduced amino acid sequence of this clone showed 71.3% homology with that of Bmlipase-1 (data not shown), suggesting that Bmlipase-1 forms a gene family.

In the final purification, 66 µg of the pure Bmlipase-1 was obtained from digestive juice of 200 B. mori larvae (data not shown), indicating that a larva contains approximately 0.33 µg of Bmlipase-1 in the digestive juice. The effect of Bmlipase-1 concentration on a fixed amount of ODV (860 ng/larva) was examined (Fig. 4). The results showed that ODV treated with more than 2.2 µg of Bmlipase-1 per larva cannot propagate at all (Fig. 4), and mortality at this concentration was 0% (data not shown). The 50% lethal dose of ODV was also calculated to be 12.0 ng/larva, with 95% confidence limits between 10.6 and 13.7 ng/larva, by the computer program PriProbit (version 1.63) by M. Sakuma (data not shown). These results indicate that endogenous Bmlipase-1 (0.33 µg/larva) can suppress infection with up to 128.7 ng of ODV per larva. However, 100% mortality was observed in larvae infected with 22 ng of ODV per larva. In the case of larvae infected with less than 5.5 ng of ODV per larva, the mortality was 0% (data not shown), suggesting that antiviral factors, including Bmlipase-1, work well when ODV concentration is less than 5.5 ng/larva. The reasons that silkworm larvae are not resistant to infection with ODV at concentrations of up to 128.7 ng/larva remain unknown. Nonetheless, it is noteworthy that the silkworm is resistant to ODV infection at concentrations of less than 5.5 ng/larva.

Gene expression of Bmlipase-1 was analyzed by Northern
in the anterior and middle portions but not in the posterior portion of the midgut (Fig. 5B). The Lip-1 gene, a *D. melanogaster* lipase gene, was demonstrated to be expressed at the foregut-midgut boundary in embryos by whole-mount in situ hybridization (10). Bmlipase-1 gene expression in fourth- and fifth-instar larvae was analyzed. The results showed that gene expression strongly declines at the molting stage between the fourth and fifth instars and at the wandering stage just before pupation (Fig. 5C), suggesting that the Bmlipase-1 gene is hormonally regulated. It is natural to consider that Bmlipase-1 is not necessary at the molting and wandering stages, because *B. mori* larvae do not ingest food during these stages. Thus, the probability of viral infection at these stages is very low. The relationship between Bmlipase-1 gene expression and BmNPV infection was examined, and viral infection was found not to activate the Bmlipase-1 gene (Fig. 5D).

In this study, we identified a protein having strong antiviral activity against BmNPV from *B. mori* larvae. The insect immune system response against NPV can be divided into two phases: primary defense against ODV in the alimentary canal and secondary defense against BV in other tissues such as the fat body, trachea, and hemocyte. Concerning the secondary defense stage, it has been shown that apoptosis is initiated during baculovirus replication in insect cells and that specific viral gene products, P35 and P49, are responsible for blocking the apoptotic response (5, 17). Moreover, it has been reported that cells of *Helicoverpa zea* larvae infected with *Autographa californica* M NPV are encapsulated by hemocytes and subsequently cleared, demonstrating that the insect cellular immune response is effective against viral pathogens (16). Although apoptosis and cellular immune responses have been shown to play an important role in the secondary defense stage against BV infection, the primary defense stage against ODV remains totally obscure. As far as we know, our results regarding Bmlipase-1 are the first demonstration that a protein from the digestive juice of the insect alimentary canal can be effective against viral pathogens.

Bmlipase-1 gene regulation is unique. Gene expression of this enzyme is not upregulated by viral infection but seems to be hormonally regulated, suggesting that the main role of the enzyme is food digestion. However, Bmlipase-1 is also involved in primary defense against viral infection to protect *B. mori* midgut epithelial cells from ODV at the initial infection stage. The antiviral mechanisms of Bmlipase-1 which suppress BmNPV replication remain unclear. *A. californica* M NPV protein P74 is associated with the ODV envelope. P74 is essential for oral infection with ODV and has been proposed to play a role in midgut attachment and/or fusion (12). It will be
interesting to determine if Bmlipase-1 destroys the virion envelope and, as a result, prevents viral attachment to the midgut through a P74 homolog. It remains to be clarified whether Bmlipase-1 inhibits multiplication of other viruses such as cytoplasmic polyhedrosis and densonucleosis viruses that are also pathogenic for *B. mori*. More proteins are likely involved in primary defense, and understanding the insect immune mechanisms against viral pathogens is important for both the silk industry and general agricultural pest control.

**Nucleotide sequence accession number.** The nucleotide sequence of Bmlipase-1 has been deposited with the DDBJ, EMBL, and GenBank Data Libraries under accession number AB076385.

We thank Toru Arakawa and Yoji Furuta for their helpful suggestions.
