Natural transmission of human immunodeficiency virus (HIV) occurs at mucosal surfaces. During acute infection, intestinal and other mucosae are preferential sites of virus replication and rapidly become depleted of CD4⁺ T cells. Therefore, mucosal immunity may be critical to control both initial infection and the massive early spread of virus. An attenuated η-alanine-requiring strain of the oral intracellular microorganism Listeria monocytogenes expressing HIV type 1 gag was shown to induce protective cell-mediated immunity in mice against viruses that express HIV gag when immunization occurs in the presence of a transient supply of η-alanine. In this study, we examined the efficacy of new attenuated strains that are able to synthesize η-alanine from a heterologous dal gene tightly regulated by an actA-promoted resolvable recombination system. In the absence of η-alanine, Gag-specific cytotoxic T lymphocytes (CTLs) were induced systemically after intravenous immunization, and one strain, Lmdd-gag/pARS, induced strong dose-dependent Gag-specific CTLs after oral immunization. A significant level of Gag-specific CD8⁺ T cells was induced in the mucosal-associated lymphoid tissues (MALTs). Upon intravaginal challenge of these orally immunized mice with recombinant vaccinia virus (rVV) expressing HIV gag, gamma interferon- and tumor necrosis factor alpha-secreting Gag-specific CD8⁺ T cells were dramatically increased in the spleen and MALTs. Oral immunization with Lmdd-gag/pARS led to complete protection against vaginal challenge by a homologous clade B gag-expressing rVV. In addition, strong cross-clade protection was seen against clades A and C and partial protection against clade G gag-expressing rVV. These results suggest that Lmdd-gag/pARS may be considered as a novel vaccine candidate for use against HIV/AIDS.

With over 42 million people currently infected, human immunodeficiency virus (HIV)/AIDS is now the most widespread pandemic in human history (52). Although HIV spreads systemically, 90% of infections are contracted through sexual transmission, with the virus crossing the mucosal lining of the genital tract, rectum, and oropharyngeal cavities (35). HIV not only subverts the immune system by rapidly infecting and depleting CD4⁺ T cells, but also becomes an integral part of the genetic material of its host’s cells. Thus, there is an urgent need for rapid intervention.

Vaccinology has made a major contribution to the eradication or management of infectious diseases (21). In developing a vaccine against HIV/AIDS, it is important to induce protective local immunity that could act at mucosal surfaces as well as in the systemic compartment. While neutralization antibodies have shown the ability to block HIV/simian immunodeficiency virus (13, 51), they are difficult to elicit. However, cellular immunity plays a critical role in controlling acute infection and maintaining a low chronic viral set point. Therefore, protective antiviral cytotoxic T lymphocytes (CTLs), particularly in the mucosal compartment, should be a major component of any immune response induced by an effective vaccine against HIV/AIDS.

Listeria monocytogenes is a gram-positive, facultative, intracellular, food-borne bacterium that has served for decades as a model pathogen for the study of cell-mediated immunity (12, 26). Subsequent to infection and uptake by phagocytic cells, unlike other intracellular organisms such as Salmonella spp. and Mycobacterium tuberculosis, a number of bacteria escape the endocytic vacuoles and replicate in the cytoplasm. Since foreign genes can be easily and stably inserted into the L. monocytogenes chromosome and express at high levels, such gene products are efficiently delivered via the major histocompatibility complex (MHC) class I and MHC class II pathways and induce strong CTL and CD4 help (4, 37, 43, 47, 50). L. monocytogenes has been explored as a live vaccine against M. tuberculosis (34), model cancers (6, 7, 20, 23, 36, 39), lymphocytic choriomeningitis (17, 48), and influenza virus infection (22). Since the natural route of L. monocytogenes infection is through the intestinal mucosa following oral ingestion of the organism, the induction of mucosal immunity is a natural consequence of infection. In fact, mice immunized orally with recombinant L. monocytogenes that expressed influenza nucleoprotein showed regression of established renal and colorectal tumors that expressed the same nucleoprotein antigen (38). Also, orally administrated recombinant L. monocytogenes strains that express the HIV type 1 (HIV-1) gag gene result in protection against challenge by recombinant vaccinia virus (rVV) expressing HIV-1 gag (rVV-gag) (46).

Preexisting immunity against a vector could interfere with the generation of an immune response against a foreign antigen expressed by that vector. However, the annual incidence of listeriosis is very low, and few individuals are expected to have preexisting immunity. In addition, existing antimicrobial immunity does not appear to inhibit the development of an *L. monocytogenes*-specific primary CTL response or diminish its therapeutic efficacy (2, 49).

Nevertheless, *L. monocytogenes* is itself a pathogen that can cause fatal infections, particularly in immunocompromised or pregnant individuals. Therefore, we have focused on methods to attenuate the organism while still retaining its immunogenicity. We initially constructed an attenuated strain, Lmdd, by deleting the two genes, *dal* and *dat*, used for D-alanine biosynthesis and cell wall formation. A recombinant, Lmdd-gag, was shown to be a safe and promising AIDS vaccine candidate (46). However, the immunogenicity of this strain is achieved by a transient supply of D-alanine provided along with the vaccine. To obviate this requirement, we constructed several derivative strains of Lmdd that are able to supply their own D-alanine but under highly restrictive conditions (29, 55). In this study, we evaluated a D-alanine-independent strain of Lmdd-gag designed to generate Gag-specific CTL responses in mucosa-associated lymphoid tissues (MALTs), which are critical for the initial control of HIV infection and spread. We showed that intragastric inoculation of mice with this new attenuated strain, Lmdd-gag/pARS, generated potent mucosal and systemic Gag-specific CTL responses. In addition, we provided new evidence that CTLs induced in the mucosal and systemic lymphoid compartments result in cross-clade protection against intravaginal virus challenge.

**MATERIALS AND METHODS**

**Bacteria and plasmids.** The double deletion strain Lmdd-gag and its wild-type parent, Lm-gag, have been described previously (15, 16). Plasmids pRRR, pKRS, and pARS (see below) were individually introduced into Lmdd-gag by electroporation according to established protocols (40), and the resulting transformants, Lmdd-gag/pRRR, Lmdd-gag/pKRS, and Lmdd-gag/pARS, were selected on brain heart infusion (BHI) agar plates containing 10 μg/ml chloramphenicol. All bacterial strains were maintained as 10^10 CFU of bacteria. The interval between immunizations was 3 weeks. Actual CFU was assessed following infection by plating dilutions of the inoculum. The animals were not fasted or neutralized for pH before immunization. All procedures used in this study complied with federal guidelines and institutional policies of the University of Pennsylvania Animal Care and Use Committee.

**Isolation of lymphocytes.** Spleens, lymph nodes (cervical, mesenteric, and iliac) and Peyers’ patches (PP) were removed from sacrificed mice. Splenocyte suspensions were obtained by pressing the tissue through a nylon mesh screen, followed by lysis of red blood cells using ACK lysis buffer (0.15 M NH4Cl, 1 mM KHCO3, 0.1 mM EDTA [pH 7.2]). Lymphocytes from pooled lymph nodes or PP were prepared as described previously (46, 54). Briefly, tissues were digested with collagenase D and DNase I at 37°C for 30 min and then incubated in the presence of 5 mM EDTA for 5 min. A single-cell suspension was prepared by teasing the digested tissues into suspension and filtering through nylon mesh to remove debris.

**Cytometric analysis.** Surface staining was performed using freshly prepared single-cell suspensions of splenocytes. The cells were stained in 1% (wt/vol) fetal calf serum (FCS)–phosphate-buffered saline (PBS) for 60 min at 4°C with fluorescent isothiocyanate-conjugated anti-CD11a (clone M17/4; eBioscience, San Diego, CA), phycoerythrin-conjugated anti-CD8 (clone 53-6.7; BD Pharmingen, San Diego, CA), and allophycocyanin-conjugated H-2K<sup>d</sup>–MHC class I–listeriolysin O<sub>1</sub>–105 (LLO<sub>1</sub>–105) or Ga<sub>1</sub>R<sub>7</sub>–205, 206 tetramers (MHCM Tetramer Core Facility, National Institute of Allergy and Infectious Diseases, Atlanta, GA) being stained, the cells were washed with PBS, fixed in 2% (wt/vol) parafomaldehyde-PBS, and analyzed with a FACSCalibur flow cytometer. The data were further analyzed using FlowJo software (Tree Star, Inc.).

**Intracellular detection of IFN-γ and TNF-α.** Intracellular cytokine staining was performed using a BD cytofix/cytoperm kit according to the manufacturer’s protocol. Briefly, lymphocytes were isolated from the indicated tissues and cultured for 5 h with Golgistop, with or without 5 μg/ml peptide. After culture, cells were stained for surface molecules and fixed, and cell membranes were permeabilized in cytofix/cytoperm solution and stained with fluorescein isothiocyanate-conjugated anti-gamma interferon (IFN-γ) (clone XMG 1.2; BD Pharmingen, San Diego, CA) and allophycocyanin-conjugated anti-tumor necrosis factor alpha (TNF-α) (clone MP6-XT22; eBioscience, San Diego, CA) in Perm/Wash solution. Cells were then washed with Perm/Wash solution, and the fluorescence intensity was measured with a FACSCalibur flow cytometer.

**CFSE labeling of cells.** Splenocytes isolated from naïve BALB/c mice were suspended in PBS at a concentration of 2 × 10<sup>7</sup> cells/ml and warm to 37°C. Cells were incubated for 10 min with 3 μM or 0.3 μM 5-(and 6-)carboxyfluorescein diacetate, succinimidyl ester (CFSE) (Molecular Probes, Eugene, OR) in the dark, and then an equal volume of 100% FCS was added and incubated at room temperature for 1 min, followed by two washes with RPMI 1640 medium with 10% FCS. **In vivo CTL assay.** The in vivo CTL assay was performed essentially as described previously (9, 55). BALB/c splenocytes were labeled with either a low (0.3 μM) (CFSE<sub>low</sub>) or a high (3 μM) (CFSE<sub>high</sub>) concentration of CFSE, and CFSE<sub>low</sub> cells were further incubated with 5 μg/ml HIV-1 Gag<sub>197–205</sub>, LLO<sub>1</sub>–105, or lymphocytic choriomeningitis virus nucleoprotein 118–126 (LCMV-NP118–126) peptides for 1 h at 37°C in the dark. Following incubation, the cells were washed, and equal numbers (1 × 10<sup>5</sup>) of each population were mixed in 200 μl of PBS and injected i.v. into previously immunized or naïve mice. Sixteen hours later, spleens from recipients were analyzed for the presence of CFSE<sub>low</sub> and CFSE<sub>high</sub> populations. In vivo killing was indicated by percent specific lysis, calculated according to the following formula: percent lysis = (1 – ratio unprimed/ratio primed) × 100, where the ratio is percent CFSE<sub>low</sub>/CFSE<sub>high</sub>.

**ELISpot assay for IFN-γ-secreting cells.** Enzyme-linked immunosopost (ELISpot) assays were conducted according to the manufacturer’s protocol (R&D Systems, Minneapolis, MN), with minor modifications. Briefly, ELISpot 96-well plates (Millipore, Bedford, MA) were coated with anti-mouse IFN-γ capture antibody (1:100 in PBS) and incubated overnight at 4°C. The following day, plates were washed and blocked for 2 h with 5% FCS. Suspensions containing 2 × 10<sup>5</sup> splenocytes in RPMI 1640 (with 10% FCS and 1 ng/ml interleukin-2) were added to each well and stimulated in triplicate, with or without peptide (5 μg/ml) or concanavalin A (2.5 μg/ml, positive control; Sigma) at 37°C. After 18 h, plates were washed and incubated overnight with biotinylated anti-mouse IFN-γ detection antibody (1:100 in 1% bovine serum albumin) at 4°C. The following day, plates were washed extensively, and BCIP (5-bromo-4-chloro-3-indolylphosphate)–ni troblue tetrazolium chromogen was added to each well to develop color. The plates were then rinsed with distilled water and dried at room temperature. Spots were counted by use of an automated ELISpot reader (CTL Limited).
describe here the immunogenicity and protection generated high level of attenuation and immunogenicity (29, 55). We monolayers with serial dilutions of virus and staining with 0.1% crystal violet. after challenge, the mice were sacrificed, and tissues were removed, homoge-

halothane-anesthetized mice (Halocarbon Laboratories, New Jersey). Six days

FIG. 1. d-alanine-independent growth (A) and virulence in mice (B) of new constructs of Lmdd-gag. (A) Bacteria were grown at 37°C in liquid BHI medium in the absence of exogenous d-alanine except where indicated (+d, 200 μg/ml of d-alanine). An aliquot of the Lmdd-gag culture (Lmdd-gag-D) was provided with d-alanine at 150 min (Lmdd-gag-D+d). The starting cultures were in the log phase of growth. OD600, optical density at 600 nm. (B) Recovery of bacteria from spleens of BALB/c mice after i.v. infection with Lm-gag, Lmdd-gag/pRRR, and Lmdd-gag/pARS in the absence of d-alanine and Lmdd-gag in the presence of d-alanine in the inoculum (Lmdd-gag-D). CFU per spleen at each time point indicates the mean number ± standard deviation of viable bacteria in the spleens of each group of three mice. The detection limit was 10 CFU.

Virus challenge. At 4 weeks after final immunization, mice were challenged systemically by intraperitoneal (i.p.) injection with approximately 1.2 × 10⁶ PFU of rVV-gag in 200 μl of PBS. Mucosal challenge was administered by an intra-
vaginal or intranasal route. Intravaginal challenge with rVV-gag was performed similarly to that previously described (11, 24, 54). Mice were subcutaneously injected with 2 mg of progesterone (Depo-Provera; Pharmacia & Upjohn, Kalamazoo, MI) and 5 days later were anesthetized through i.p. injection of ketamine (150 mg/kg of body weight; Sigma) and xylazine (10 mg/kg; Sigma) in 0.9% NaCl and infected intravaginally for 1 h with rVV-gag (approximately 6 × 10⁶ PFU; provided by the NIH AIDS Research and Reference Reagent Program) in 20 μl of PBS while being maintained under anesthesia. For intranasal challenge, 10⁷ PFU of rVV-gag in 10 μl was delivered to the nares of halothane-anesthetized mice (Halocarbon Laboratories, New Jersey). Six days after challenge, the mice were sacrificed, and tissues were removed, homoge-

nized in nylon mesh, and assayed for virus content by infection of BSC-1 cell monolayers with serial dilutions of virus and staining with 0.1% crystal violet.

RESULTS

New vaccine strain of recombinant L. monocytogenes expressing HIV-1 gag. In earlier studies, a highly attenuated strain of L. monocytogenes, Lmdd-gag, that expressed HIV-1 gag and carried deletions of two chromosomal genes (dal and dat) was shown to induce long-lasting protective cell-mediated immunity against a viral agent expressing Gag (44–46). dal and dat are required by L. monocytogenes for d-alanine biosynthe-

sis, cell wall formation, and growth. The immunogenicity of Lmdd-gag depended on a minimal level of bacterial replication that was achieved with a transient exogenous supply of d-alanine provided along with the vaccine. Consequently, comparable infection of monkeys or humans would require paren-
teral administration of significant quantities of d-alanine. While this compound appears to be safe in the small rodent and in rhesus macaques (unpublished observations), its safety in humans is unknown.

These considerations prompted us to devise ways to allow transient endogenous synthesis of d-alanine while retaining a high level of attenuation and immunogenicity (29, 55). We describe here the immunogenicity and protection generated by a derivative of Lmdd-gag in which the transient supply of d-alanine is provided by a dal gene-carrying plasmid from which the dal gene is excised during cytosolic growth of the bacteria through the action of the res/resolvase recombination system. As shown later, in order to achieve a sufficiently robust cellular immune response following oral vaccination, we needed to reduce the high activity of the resolvase enzyme (on plasmid pRRR) by introducing into the protein a destabilizing peptide sequence encoded by ssrA (18, 25) (generating plasmid pKRS). We also transferred this recombination system onto the more stable plasmid pAM401 (generating plasmid pARS). The resulting bacteria were designated Lmdd-gag/pRRR, Lmdd-gag/pKRS, and Lmdd-gag/pARS. All three recombinant L. monocytogenes strains contain the same clade B HIV-1 gag gene in their chromosomes, express a Bacillus subtilis dal gene, and synthesize d-alanine under the stringent regulation of an actA-promoted resolvase recombination system (55).

Figure 1A shows that all of the new strains grew in bacteri-

ological media in the absence of d-alanine at only slightly lower rates than wild-type Lm-gag (15) or Lmdd-gag plus d-alanine (16, 46). Nevertheless, these organisms were attenuated in mice, as shown in Fig. 1B, which indicates that they survived for only 3 days following i.v. infection. Thus, while the wild-type Lm-gag recombinant bacteria were increasing in number in spleen at days 2 and 3 after infection, the viability of the attenu-
ated strains had fallen 3 to 5 log₁₀. As anticipated, the presence of the destabilizing ssrA peptide sequence on the resolvase enzyme of Lmdd-gag/pARS allowed these bacteria to survive slightly longer in mice than Lmdd-gag/pRRR. Additional character-
ization of these strains revealed that whereas they could replicate for 10 h or longer within the cytoplasm of macrophage-like J774 cells, they did not survive sufficiently long (3 to 4 days) to form plaques (55) on monolayers of mouse L2 fibroblasts (data not shown).

Induction of antigen-specific CTLs in the spleen after sys-
temic immunization with Lmdd-gag derivative strains. The
were coated with either Gag197–205 peptide or a control peptide. Splenocytes labeled with a high concentration of CFSE and 10.2% LLO-specific CD8 T cells were isolated and stained for the presence of antigen-specific CD8 T cells. With the lowest dose (2×10^7 CFU), although LLO-specific CD8 T cells were readily detected, Gag-specific CD8 T cells scarcely exceeded background levels. The highest dose (10^{10} CFU)

VOL. 80, 2006 VAGINAL PROTECTION AFTER ORAL LISTERIA IMMUNIZATION 8883

FIG. 2. Comparable Gag-specific and LLO-specific CTLs are generated in the spleens of mice immunized i.v. with Lmdd-gag and derivative strains. (A) BALB/c mice were left unimmunized or immunized twice through the tail vein with 10^7 (primary) and then 10^8 (boost) CFU of the recombinant L. monocytogenes bacteria. Only Lmdd-gag was given along with 10 mg D-alanine in the inoculum. The interval between the prime and boost was 3 weeks. The frequencies of CD8 T cells specific for LLO_{91-99} and Gag_{197-205} were determined by tetramer staining at 6 days after the boost. Plots shown are of gated CD8 T cells and are representative of two to three mice used for each group. (B) Mice were immunized as described for panel A. Six days after the boost, a total of 2×10^7 cells containing equal numbers (#) of CFSE^{high} (peptide Gag_{197-205} or LCMV-NP_{118-126}-coated) and CFSE^{low} (uncoated) spleen cells were coinjected into immunized or immunized BALB/c mice, and in vivo cytosis of CFSE-labeled donor cells was assessed 16 h later. The percent lysis value was calculated as described in Materials and Methods. Individual percentages of CFSE^{high} or CFSE^{low} splenocytes in the recipient mice are shown (as gated on CFSE T cells in small font).

50% lethal dose of Lmdd-gag as well as that of the three new derivative strains was approximately 1×10^8 to 2×10^8 CFU/mouse (data not shown). To determine whether the new strains, like Lmdd plus D-alanine, could induce protective CD8 T cells in the absence of D-alanine, we first examined CD8 T-cell activation in the spleens of systemically immunized mice. Groups of mice were immunized through the tail vein with a sublethal dose (10^7) of recombinant bacteria and boosted with 10^8 of the same bacteria. Six days later, splenocytes were isolated and stained for the presence of antigen-specific CD8 T cells by use of Gag_{197-205} or LLO_{91-99} H-2K^d tetramers to detect the dominant CD8 T-cell response to each of these antigens in BALB/c mice (8, 30). As shown in Fig. 2A, robust expansion of antigen-specific CD8 T cells was seen. Most of these cells showed high expression of CD11a, a β2 integrin up-regulated upon activation of CD8 T cells and present at high levels on memory CD8 T cells (27). In the absence of D-alanine, Lmdd-gag induced 1.12% Gag-specific and 10.2% LLO-specific CD8 T cells in the spleen, while in the absence of D-alanine, Lmdd-gag/pRRR and Lmdd-gag/pKRS induced comparable levels of GAG-specific (1.09% and 1.35%) and LLO-specific (10.1% and 12.1%) CD8 T cells. Lmdd-gag/pARS induced the highest percentages of antigen-specific (1.55% Gag-specific and 13.1% LLO-specific) CD8 T cells. In summary, like Lmdd-gag with exogenous D-alanine, Lmdd-gag derivative strains were all able to stimulate substantial antigen-specific CD8 T-cell responses without exogenous D-alanine, despite showing a 50% lethal dose similar to that of Lmdd-gag.

To determine whether the induced Gag-specific CD8 T cells retained effector functions, we measured the in vivo epitope-specific cytolitic activities of CD8 T cells in mice immunized systemically with Lmdd-gag/pRRR as described above. Splenocytes labeled with a high concentration of CFSE were coated with either Gag_{197-205} peptide or a control peptide, LCMV-NP_{118-126} and coinjected with equal numbers of non-peptide-coated splenocytes labeled with a lower concentration of CFSE into immunized mice at day 6 after the booster infection. After 16 h, the ratio of CFSE^{high} (peptide-coated): CFSE^{low} (no peptide) cells served as an indication of CTL activity. As shown in Fig. 2B, robust Gag-specific killing occurred in both Lmdd-gag (79% lysis of targets)- and Lmdd-gag/pRRR (79.5% lysis of targets)-immunized mice, while no killing was detected in unimmunized mice. As expected, we detected little lysis of LCMV-NP_{118-126}-coated splenocytes. These results suggested that systemic immunization with Lmdd-gag derivatives in the absence of D-alanine could generate functional CTLs.

Induction of antigen-specific CTLs in the spleen and MALTs after oral immunization with Lmdd-gag/pARS. To examine the induction of antigen-specific CD8 T-cell responses in the spleens of orally immunized mice, groups of mice were immunized by gavage to deliver a single oral dose of 2×10^7 CFU of recombinant L. monocytogenes. Six days later, as shown in Fig. 3A, both Lmdd-gag/pKRS and Lmdd-gag/pARS, but not Lmdd-gag/pRRR, induced significant levels of Gag-specific (0.27% and 0.33%) CD8 T cells. Levels of LLO-specific CD8 T cells were high in all immunized mice, but again Lmdd-gag/pRRR showed the lowest response. The response produced by Lmdd-gag/pARS was comparable to that produced by Lmdd-gag plus D-alanine.

Therefore, subsequent experiments focused on Lmdd-gag/pARS. Figure 3B illustrates the relationship between the immunization dose and the magnitude of antigen-specific CD8 T cells induced in the spleen and shows that increased numbers of recombinant Lmdd-gag/pARS delivered orally resulted in increased numbers of antigen-specific CD8 T cells. With the lowest dose (2×10^7 CFU), although LLO-specific CD8 T cells were readily detected, Gag-specific CD8 T cells scarcely exceeded background levels. The highest dose (10^{10} CFU)
induced 0.61% Gag-specific and 1.06% LLO-specific CD8+ T cells. Based on these results, in subsequent oral immunization experiments we used 2 \times 10^9 CFU of Lmdd-gag/pARS for primary immunizations and 10^{10} CFU for boosts.

Since protection against HIV infection is likely to require immunity at mucosal sites, we further examined whether antigen-specific CD8+ T cells could be induced in MALTs, such as mesenteric lymph nodes (MLN) and PP. Groups of mice were fed 2 \times 10^9 CFU bacteria for a primary immunization and 10^{10} CFU bacteria for a boost. Six days later, lymphocytes were isolated from MLN, PP, and spleens and analyzed for antigen-specific CD8+ T cells by use of tetramer staining. As shown in Fig. 3C, all tissues of immunized mice contained significant numbers of Gag-specific and LLO-specific CD8+ T cells, with spleens containing the highest percentages. In MLN and PP, antigen-specific CD8+ T cells were detectable only after the boost despite the fact that large numbers of Lmdd-gag/pARS were found in these tissues at days 1 and 3 after initial infection (data not shown). Unlike results for spleen, the numbers of Gag- and LLO-specific CD8+ T cells were equivalent in MLN and PP. In unimmunized mice, only background levels of tetramer-positive cells were detected in any tissue.

To test whether the antigen-specific CD8+ T cells induced by oral immunization with Lmdd-gag/pARS possess effector functions, we measured the in vivo cytolytic activities of these animals. Groups of mice were fed 2 \times 10^9 CFU bacteria and boosted twice with 10^{10} CFU Lmdd-gag/pARS. At day 6 after the last immunization, a total of 2 \times 10^7 cells containing equal numbers (#) of peptide-coated CFSE high and peptide-uncoated CFSE low spleen cells were coinjected into unimmunized or immunized BALB/c mice, and in vivo cytolysis of CFSE-labeled donor cells was assessed 16 h later. The percent lysis value was calculated as described in Materials and Methods. Individual percentages of CFSE_{high} and CFSE_{low} splenocytes in the recipient mice are shown (small font). Peptides used to coat spleen cells were Gag197–205, LLO91–99, and LCMV-NP118–126.
lated spleen cells from mice that had been immunized orally three times as described above and rested for 8 weeks after the last vaccination. As shown in Fig. 5, substantial and comparable numbers of Gag-specific and LLO-specific IFN-γ-secreting cells were detected in the Lmdd-gag/pARS (without D-alanine)- and Lmdd-gag (with D-alanine)-immunized mice, whereas only a few nonspecific spots were detected in response to the unrelated LCMV-NP peptide. Depletion of CD8+ T cells from the splenocytes before antigen-specific stimulation resulted in complete loss of IFN-γ secretion. These data indicate that oral immunization with Lmdd-gag/pARS in the absence of D-alanine induced a pool of systemic antigen-specific memory CD8+ T cells.

We subsequently determined whether these memory CD8+ T cells could mount a recall response following challenge with an HIV-1 gag-expressing virus. Since mice are not susceptible to HIV infection, we used a surrogate virus—recombinant vaccinia virus expressing HIV-1 gag from clade B (rVV-gag, VVK1). Mice that received three oral doses of Lmdd-gag/pARS were challenged with VVK1 either systemically (i.p., 1 x 10^6 PFU), intravaginally (IVAG, 8 x 10^7 PFU), or intranasally (i.n., 1 x 10^7 PFU) with vaccinia virus expressing HIV-1 gag from clade B (VVK1). Controls were unimmunized (Naïve) or age-matched animals that had been infected only with rVV-gag (VVK1). Six days after challenge, splenocytes from unchallenged (A) or challenged (B) mice were isolated and measured for Gag-specific CD8+ T cells by tetramer staining. (C) Splenocytes from IVAG-challenged mice were assayed for IFN-γ and TNF-α production following Gag 197–205 peptide stimulation using intracellular staining. Plots shown in panels B and C are gated CD8 cells and are representative of two to three mice per group.

gardless of the route of infection, resulted in the induction of a primary effector population that contained only a small number (0.14 to 0.37%) of Gag-specific CD8+ T cells.

When the CD8+ T cells were restimulated with Gag 197–205 peptide and analyzed for IFN-γ and TNF-α production, we found that the majority of activated CD8+ T cells produced both of these inflammatory cytokines in response to peptide (Fig. 6C). There was no response in the absence of peptide or response to the unrelated LCMV peptide (data not shown). Consistent with the tetramer staining results, cells from mice infected only with VVK1 produced only low levels of cytokine.
we examined the presence of Gag-specific CD8 T1 cells in the tissues (PP, MLN, and ILN). Moreover, intravaginal challenge induced much higher responses in all other tissues than after intranasal challenge, while intranasal challenge induced significant levels of Gag-specific CD8 T1 cells in the CLN. These data indicate that mucosal challenge of mice immunized orally with Lmdd-gag/pARS induced strong Gag-specific CD8 T1-cell recall responses in the MALTs.

Thus, the Gag-specific memory CD8 T1 cells induced by oral immunization with Lmdd-gag/pARS were capable of dramatically expanding into effector CD8 T1 cells upon rVV-gag challenge.

To further address mucosal immunity after virus challenge, we examined the presence of Gag-specific CD8 T1 cells in the MALTs, including PP, MLN, cervical lymph nodes (CLN), and iliac lymph nodes (ILN), at day 6 after challenge. The experiments illustrated in Table 1, carried out using tetramer staining, showed that both intranasal and intravaginal challenges induced significant levels of Gag-specific CD8 T1 cells in all tissues examined. The response in CLN was higher after intranasal challenge than after intravaginal challenge, while intravaginal challenge induced much higher responses in allother tissues (PP, MLN, and ILN). Moreover, intravaginal challenge induced the highest level (~4.6%) of Gag-specific CD8 T1 cells in the CLN, which enlarged dramatically after virus challenge. The majority of Gag-specific CD8 T1 cells in the MALTs resulted from rapidly expanded memory CD8 T1-cell populations, since the tissues contained significant numbers of memory T1 cells prior to challenge (0.38 to 0.48%), and VVK1 infection of naive mice resulted in levels of Gag-specific CD8 T1 cells that were only slightly higher than the background staining levels for the naive animals (Table 1). Taken together, these data indicate that mucosal challenge of mice immunized orally with Lmdd-gag/pARS induced strong Gag-specific CD8 T1-cell recall responses in the MALTs.

Protection against systemic and mucosal virus challenges. Finally, we determined the efficacy of the immunity induced by the oral Lmdd-gag/pARS vaccine to protect against a mucosal challenge by rVV-gag by either the intravaginal or intranasal route. Mice were orally immunized three times and then challenged with rVV-gag (VVK1 or VP1287) expressing a homologous clade B gag gene. Six days after the challenge, mice were sacrificed and tissues were assayed for virus content.

In naive, nonimmune mice, high titers of virus were consistently found in ovaries after i.p. infection (Fig. 7A) and intravaginal infection (Fig. 7B), in agreement with previous reports that the virus has a tropism for the ovary (1). However, following intranasal infection, no virus was found in ovaries. Rather, a modest level of virus (4 log10 PFU) was seen in the lung (Fig. 7A) and occasionally in the draining cervical lymph node (data not shown). Surprisingly, we found that intravaginal infection, but not i.p. infection, resulted in a log10-higher titer of virus in the oviduct than in the ovaries (Fig. 7B), indicating that this tissue is an even more preferred site for virus replication following vaginal infection. Little virus was detected in the oviduct after i.p. infection (Fig. 7C).

Figure 7A compares the effects of oral and systemic immunization with Lmdd-gag/pARS on the level of virus in ovaries after a systemic virus challenge. Although mice immunized by the i.v. route were completely protected against i.p. challenge, orally immunized mice showed only a 2- to 3-log10 reduction in virus titer in the ovaries. This is consistent with previous observations that oral immunization with recombinant L. monocytogenes expressing HIV-1 gag produced complete protection...
against mucosal but not systemic challenge by rVV-gag (46). Figure 7A also shows that oral immunization led to partial protection against virus replication in the lung, the apparent target organ after nasal infection by the virus. Not discernible from the mean value shown in the figure is that four of the five intranasally challenged mice in this experiment were fully protected.

As shown in Fig. 7B, oral immunization with Lmdd-gag/pARS completely protected mice against an intravaginal challenge, as indicated by the 6-log10 reduction in virus titer in oviduct and the 4- to 5-log10 reduction in titer in ovaries, compared with titers in unimmunized control animals. As expected, no protection against challenge with vaccinia virus expressing a nef gene was observed in immune mice (data not shown). Figure 7C further confirms that virus replication in ovaries following systemic virus challenge (using two different clade B gag-expressing viruses) is only partially inhibited after oral immunization. Figure 7C also shows that there was little replication of virus in oviduct following this i.p. route of challenge.

Finally, to determine whether the oral immunization with Lmdd-gag/pARS could induce cross-clade protection, orally immunized mice were challenged intravaginally with rVV expressing HIV gag from different clades. As shown in Fig. 8, the clade B Gag of Lmdd-gag/pARS generated strong cross-clade protection against both clades A and C but weaker protection against a clade G rVV-gag. Incomplete intravaginal protection against VT196, one of the two clade C gag-expressing rVVs used in this study, was observed, possibly due to a greater virulence of VT196 than VT369. Indeed, systemic infection with VT196 resulted in a 2-log10-greater virus titer in ovaries than infection with VT369 (Fig. 8B). Curiously, the replication of the clade A gag-expressing rVV, but not the other viruses, was almost completely blocked during a systemic i.p. challenge.

**DISCUSSION**

HIV transmission occurs predominantly through sexual exposure of mucosal surfaces of the genital tract and rectum to virus and virus-infected cells. Recent studies have shown that the mucosal system, particularly the gastrointestinal immune system, is the major target for HIV infection and replication at early stages, with more than 50% of memory T cells destroyed at this site within the first 2 weeks of infection (5, 19, 28, 31, 33). These findings imply that the induction of strong virus-specific immunity at mucosal sites may be crucial for an effective AIDS vaccine. Consequently, while the challenge remains to induce neutralizing antibodies, there is now a major effort to develop vaccines that maximize cell-mediated mucosal immunity, especially in the intestine and genital tract. Although mucosal immunity can be induced by many parenterally administered vaccines, a more robust response is usually elicited by vaccines that act at the oral, nasal, vaginal, or rectal mucosa.

*Listeria monocytogenes* is therefore an attractive vaccine vehicle since it naturally infects after oral ingestion and induces strong innate immune responses and potent mucosal and systemic cell-mediated adaptive immunity. In the present study, mice orally immunized with attenuated recombinant *Listeria monocytogenes* bacteria responded with functional Gag-specific CD8+ T-cell responses following mucosal and systemic immunization (Fig. 2)
and 3). We found that systemic (i.v.) immunization with all three induced similar CD8+ T-cell responses in the spleen, comparable to that induced by the original d-alanine-dependent strain, Lmdd-gag. However, after mucosal immunization, only Lmdd-gag/pARS induced substantial CD8+ T-cell responses in the spleen and MALTs. Therefore, the largest difference in immunogenicity among the three vaccines was detected after oral immunization, whereas after systemic infection, this difference was not significant, suggesting that the gastric route presents a more demanding environment for the bacteria. Furthermore, we showed that induction of antigen-specific CD8+ T cells in the spleen is dose dependent after oral immunization: high bacterial doses resulted in consistent induction of a higher percentage of antigen-specific CD8+ T cells, while low doses resulted in lower and more-varied levels of responses (Fig. 3B). Therefore, most oral immunization experiments were initiated with a moderate dose of bacteria (2 × 10^7 CFU) and then boosted with a fivefold-higher dose (10^10 CFU). This regimen induced substantial antigen-specific CD8+ T cells in Peyer’s patches, mesenteric lymph nodes, and spleens (Fig. 3C), whereas priming alone generated barely detectable responses in these tissues, consistent with others’ findings (42). The responses were strongly boosted by intranasal or intravaginal virus challenge with vaccinia virus expressing a homologous gag gene (Fig. 6B and Table 1). Viral infection alone induced very low levels of antigen-specific CD8+ T cells.

We and others (15, 41, 45, 46) have shown that antigen-specific CD8+ T cells are induced by wild-type and attenuated L. monocytogenes strains by use of 31Cr release in vitro CTL measurements, Gag/LLO tetramer binding assays, and peptide-stimulated IFN-γ intracellular staining. In this study, we also sought to determine whether the new constructs could elicit a CTL response detectable in vivo, an activity likely to be necessary in the control of an HIV infection. This study is the first to use this more sensitive assay to evaluate the endogenous Gag-specific CTL activity induced by an oral L. monocytogenes vaccine. In fact, in vivo lysis of antigen-labeled target cells was detected after oral immunization with both Lmdd-gag and Lmdd-gag/pARS (Fig. 4). Interestingly, unlike a previously reported study (41), we detected similar levels of Gag-specific and LLO-specific CD8+ T cells in MLN and PP (Fig. 3C), whereas a higher level of LLO-specific CD8+ T cells was consistently observed in the spleen after oral immunization (Fig. 3A to C). This suggested that Gag and LLO antigen presentation might be organ specific after oral immunization and that an attenuated strain of L. monocytogenes expressing HIV-1 Gag might disseminate systemically differently from wild-type Lm-gag.

Although L. monocytogenes has been explored as an oral vaccine against several infectious diseases, it is not known whether it induces effective immune responses at mucosal surfaces other than the gastrointestinal tract, particularly since the respiratory and genital tracts are major routes of entry of many human pathogens. Since CD8+ T-cell responses in mucosal tissues are difficult to assess, such responses are often measured in the lymph nodes draining mucosal tissues. Expansion of Gag-specific CD8+ T cells in the spleen and lymph nodes draining the respiratory tract (cervical lymph node) and the genital tract (iliac lymph node) was observed following oral immunization with Lmdd-gag/pARS (Table 1). These responses were strikingly augmented following infection with an rVV expressing a homologous gag gene (VVK1 or VP1287), administered through either the intranasal or the intravaginal route. This suggests that effective mucosal immune responses can be induced at those sites after oral immunization. Importantly, the dramatically increased frequency of Gag-specific CD8+ T cells in the iliac lymph node would be expected to translate into protection against intravaginal virus challenge. Our preliminary studies have shown that the nasal mucosa is more sensitive than the gut to infection and translocation by L. monocytogenes (unpublished data). It is therefore of interest to determine whether nasal infection with L. monocytogenes induces vaginal and intestinal responses in mice.

HIV genetic diversity has been a major challenge to the development and evaluation of effective HIV vaccines, since HIV exhibits a high frequency of mutation and leads to recombinant formation following superinfection. The three major groups of HIV have been subdivided into 11 clades. In this study, we showed that immunization with Lmdd-gag/pARS expressing HIV-1 clade B gag induced cross-clade protection against intravaginal challenge with rVV expressing HIV-1 gag from clades A and C but only weak protection against clade G (Fig. 8). In addition, when orally immunized mice were systematically challenged with virus, a 4-log10 reduction in virus titer of clade A gag-expressing rVV was observed, comparable to that of clade B gag-expressing rVV, whereas only a minor reduction in virus titer occurred in mice challenged with clade C gag- or clade G gag-expressing virus. The cross-protection is most likely mediated by CTLs recognizing closely similar H2-Kd-restricted Gag-specific CTL epitopes shared between clades A, B, and C but presented less efficiently by clade G. Our data support but are slightly different from a previously published report that a clade G Gag-specific cell-mediated immunity was found to be cross-protective with clades A and C but not clade B (24). Nevertheless, a clade B-based HIV-1 vaccine was shown to be capable of inducing cross-clade immunity in uninfected volunteers (14). Cross-clade immunity to Gag, Nef, and Env has also been reported to occur in HIV-1-infected individuals (10, 32).

In conclusion, this mouse study makes the novel observation that a new oral L. monocytogenes-based vaccine expressing the HIV gag gene induced strong antigen-specific protective CTL responses in the mucosal immune system and cross-clade protection against intravaginal virus challenge. Recent studies have already revealed that oral immunization of rhesus macaques with recombinant strains of L. monocytogenes can be effective inducers of cellular immune responses in this nonhuman primate model (3; S. Jiang, R. Rasmussen, K. McGeehan, F. Frankel, J. Lieberman, H. McClure, K. Williams, U. Babu, R. Raybourne, E. Strobert, and R. Ruprecht, submitted for publication). While the mouse model has served to prove our concept, in general it is unreliable for assessing immunogenicity in nonhuman primates and humans. We therefore look forward to further evaluation of Lmdd-gag/pARS in monkeys, where it may prove to be a particularly safe and effective mucosal vaccine against HIV/AIDS. These results may also have important implications in the development and evaluation of mucosal vaccines against other sexually transmitted diseases, such as herpes simplex virus.
