Received 15 June 2005/Accepted 21 October 2005

Porcine reproductive and respiratory syndrome (PRRS) is the most important disease causing serious economic losses to the swine industry. Since it was first described in 1987 in the United States as a “mystery swine syndrome,” PRRS has continued to cause severe reproductive failure in sows and respiratory problems in young piglets (8). PRRS virus (PRRSV), the causative agent of PRRS, is a member of the family Arteriviridae, grouped together with the Coronaviridae and Toroviridae in the order Nidovirales (6). Other members of this family are equine arteritis virus, lactate dehydrogenase-elevating virus of mice, and simian hemorrhagic fever virus (33). PRRSV has a highly restricted cell tropism both in vivo and in vitro. PRRSV infects the African green monkey kidney cell line, MA-104 and its derivatives, MARC-145, and CL-2621 in vitro (23). PRRSV preferentially infects the cells of the monocyte/macrophage lineage, especially porcine alveolar macrophages (PAM), in the natural host (13). PRRSV enters host cells through a mechanism of receptor-mediated endocytosis. The entry mechanism is mediated by attachment to one or more cellular receptors and/or coreceptors, which are important determinants of the highly restricted cell tropism (25). To date, only two molecules have been described as putative receptors. One candidate is heparan sulfate (HS). However, addition of soluble HS did not completely block binding and infection of PRRSV, even though it seems to play an important role in the virus infection of PAM (11). The other candidate is sialoadhesin (Sn), which was previously described as a 210-kDa protein (p210) immunoprecipitated by PRRSV blocking monoclonal antibody (MAb) (MAb41D3) on PAM. However, transfection of Sn cDNA did not fully engender PRRSV susceptibility in CRFK cells, even though its antibody (Ab) completely blocked infection (10, 12, 39). Both HS and Sn, which are involved in PRRSV infection of PAM, are not expressed on MARC-145 cells.

In this study, we found that PRRSV binds to vimentin, an intermediate-filament (IF) protein, and anti-vimentin Abs block PRRSV infection of MARC-145 cells. When simian vimentin was delivered to BHK-21 and CRFK cells, they became susceptible to PRRSV. Vimentin is also thought to be involved in the replication and transportation of PRRSV inside the cell by forming a complex with the other components of the intermediate filaments.

MATERIALS AND METHODS

Cell lines and virus. Cell lines used in this study were derivatives of the African green monkey kidney (MARC-145 and Vero), baby hamster kidney (BHK-21), Crandall Rees feline kidney (CRFK), porcine kidney (PK-15), swine testicle (ST), and Maden-Darby canine kidney (MDCK) cell lines. The cell lines were grown in Eagle’s minimum essential medium (Life Technologies, Inc., Gaithersburg, MD) supplemented with 10% fetal bovine serum (FBS) (HyClone, Logan, UT). The ATCC VR 2323 strain of PRRSV was used in the study.

32P-labeled RNA probe preparation. α-32P-labeled 3 untranslated region RNA transcript was prepared by in vitro transcription using a T7 RNA synthesis kit (Riboscribe Epicenter Technologies, Madison, WI), by following the manufacturer’s instructions. The probe was purified by Quick Spin columns (Boehringer Mannheim, Indianapolis, IN).

North-Western blotting of RNA-binding proteins. To screen PRRSV 3 untranslated region RNA-binding proteins, North-Western blot analysis was performed. Cytoplasmic protein extracts of PRRSV-infected MARC-145 cells were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). After the proteins were transferred onto a nitrocellulose membrane (Gelman Sciences, Ann Arbor, MI), the membrane was denatured in 6 M guanidinium hydrochloride for 30 min, followed by sequential renaturation every 10 min with changes of single-binding (SB) buffer (0.05 M NaCl, 10 mM Tris [pH 7.0], 1 mM EDTA, 0.02% [wt/vol] bovine serum albumin, 0.02% [wt/vol] Ficoll,
and 0.02% [wt/vol] polyvinyl pyrrolidone). Hybridization was performed in SB buffer containing 38-labeled RNA probe at 500,000 cpm/ml in the presence of 10 µg/ml of yeast RNA and 100 µg/ml of denatured sheared sperm DNA overnight. The membrane was washed three times with SB buffer for 30 min and then visualized by autoradiography.

Production and characterization of 7G10 MAb. The desired protein band on the X-ray film was aligned to a Ponceau S-stained nitrocellulose membrane, and then the band (57 kDa) was excised from the membrane. The protein was eluted from the membrane with 500 µl of elution buffer (1% Triton X-100 in 50 mM Tris-HCl, pH 9.5) per cm² of the membrane and injected five times at weekly intervals to a BALB/c mouse, along with RIBI adjuvant (RIBI ImmunoChem Research, Inc., Hamilton, MT). Three days before fusion, the mouse was boosted with antigen. The spleen cells were collected and fused with Ag-8 cells. The fused cells were in a hypoxanthine-aminopterin-thymidine medium with 20% FBS and 5% hybridoma cloning factor (Fisher Scientific, Pittsburgh, PA) were dispensed into a 96-well tissue culture plate and incubated at 37°C. The MAb supernatants were screened by enzyme-linked immunosorbent assay. Immunol 1 96-well flat-bottom plates (Dynatech Technologies, Chantilly, VA) were coated with the cytoplasmic proteins of MARC-145 cells, and then each supernatant was used as a primary Ab after being blocked with 0.5% glycine in PBS. The peroxidase-conjugated horse anti-mouse immunoglobulin G (heavy and light chains) (IgG [H+L]) (Vector Laboratories, Inc., Burlingame, CA) was used as a secondary Ab. The presence of 7G10 MAb was detected by the addition of TMB microwell peroxidase substrate (one component) (KPL, Gaithersburg, MD). To confirm the specificity of the 7G10 MAb, Western blot analysis was performed. The cytoplasmic proteins of MARC-145 cells were separated by SDS-PAGE, and 7G10 MAb was used as a primary Ab after it was blocked with 5% skim milk in PBS. The peroxidase-conjugated horse anti-mouse IgG (H+L) (KPL, Gaithersburg, MD) was used as a secondary Ab. The band was detected by the addition of TMB membrane peroxidase substrate (one component) (KPL, Gaithersburg, MD).

Purification of 7G10 MAb-bound proteins. A PRRSV blocking MAb (7G10) was affinity purified using KAPTV-AE (Tecnogen S. C. P. A., Piana di Montel Verna [CE], Italy), following the manufacturer's instructions. The purified 7G10 MAb was cross-linked to the Affi-Gel active beads (Bio-Rad, Hercules, CA) according to the manufacturer's instructions. The beads were loaded into a column and washed with cold water (3 ml). Approximately 5 mg of 7G10 MAb per ml of beads was mixed and incubated at 4°C overnight. The beads were washed twice with 50 mM sodium phosphate (pH 7.5) and once with 50 mM sodium phosphate (pH 7.5) containing 1 M sodium chloride and blocked by the addition of 100 mM ethanamine-HCl (pH 7.5) at 4°C overnight, followed by washing with PBS. MARC-145 cytoplasmic proteins were applied to the column and washed with 10 mM sodium phosphate (pH 6.5). The 7G10 MAb-bound proteins were eluted by adding 1 ml of 100 mM glycine (pH 2.5), and the eluted solution was neutralized with 100 µl of 1 M phosphate buffer (pH 8.0).

Plaque reduction assay. PRRSV was titrated by plaque reduction assay in MARC-145 cell cultures that were preincubated with 7G10 MAb. MARC-145 cells were cultured overnight in a six-well tissue culture plate (2.5 x 10⁵ cells/well). The supernatant of cells was harvested, and the virus was harvested 3 to 4 days postinfection, fixed with cold 80% acetone at 4°C for 10 min, and then the virus was washed with PBS three times and incubated with SR-30 (Rural Technologies, Inc., Brookings, SD) at room temperature for 1 h. The membrane was washed with PBS three times, and the presence of virus binding to vimentin was detected by the addition of TMB membrane peroxidase substrate (one component).

Total cellular protein isolation. The total cellular proteins were isolated from MARC-145, BIHK-21, CRFk, MDCK, PK-15, ST, and Vero cells in the gels. Two-dimensional (2-D) electrophoresis. In-gel tryptic digestion, MALDI-TOF MS, and analysis of peptide sequences. Reverse transcription was performed at 42°C for 45 min, 95°C for 10 min, and then the reaction was initially diluted 1:10 and in 10-fold dilutions thereafter. The cells were harvested 3 to 4 days postinfection, fixed with cold 80% acetone at 4°C for 10 min, and then incubated at 37°C for 30 min with fluorescein isothiocyanate (FITC)-conjugated SDWO-17 (Rural Technologies, Inc., Brookings, SD) at room temperature for 1 h. MARC-145 cell cultures that were preincubated with 7G10 MAb. MARC-145 cells were cultured overnight in a 96-well tissue culture plate (1 x 10⁵ cells/well). The cells were incubated with PRRSV, which were preincubated with either polyclonal rabbit anti-human vimentin Ab (Biomeda Corporation, Foster City, CA) or monoclonal anti-β-galactosidase Ab (Boehringer Mannheim, Indianapolis, IN). The antibodies were prepared as serial twofold dilutions starting with a 1:20 dilution, and the PRRSV preparation was initially diluted 1:10 and in 10-fold dilutions thereafter. The cells were harvested 3 to 4 days postinfection, fixed with cold 80% acetone at 4°C for 10 min, and then the membrane was washed with 0.05% Tween-20 PBS three times, and the presence of vimentin was detected by the addition of TMB membrane peroxidase substrate (one component).

Checkeorder titration assay for measuring blocking activity of anti-vimentin Ab. To examine the blocking activity of anti-vimentin Ab, a checkerboard titration assay was performed. MARC-145 cells were cultured overnight in a 96-well tissue culture plate (1 x 10⁵ cells/well). The cells were incubated with PRRSV, which were preincubated with either polyclonal rabbit anti-human vimentin Ab (Biomeda Corporation, Foster City, CA) or monoclonal anti-β-galactosidase Ab (Boehringer Mannheim, Indianapolis, IN). The antibodies were prepared as serial twofold dilutions starting with a 1:20 dilution, and the PRRSV preparation was initially diluted 1:10 and in 10-fold dilutions thereafter. The cells were harvested 3 to 4 days postinfection, fixed with cold 80% acetone at 4°C for 10 min, and then the membrane was washed with 0.05% Tween-20 PBS three times, and the presence of vimentin was detected by the addition of TMB membrane peroxidase substrate (one component).
PRRSV RNA production in cells, RT-PCR was performed. RNA was isolated with the RNeasy Mini Kit (QIAGEN, Valencia, CA). RT-PCR was performed using a OneStep RT-PCR kit (QIAGEN, Valencia, CA) with forward (5'-GGT CGCATTTCACCTGGTA-3') and reverse (5'-TCAATCCAGGCTAAGGT TG-3') primers. The reverse transcription reaction was done at 50°C for 30 min, and the initial PCR was done at 95°C for 15 min. Standard PCR was done at 94°C for 30 s, 55°C for 30 s, and 72°C for 60 s for 30 cycles and at 72°C for 30 min.

Cloning of the RT-PCR product from RNA of ST cells. The RT-PCR product was purified with a Clontech NucleoTrap gel extraction kit (Clontech Laboratories, Inc., Palo Alto, CA). Purified cDNA was cloned with the pGEM-T Easy vector system I (Promega Corporation, Madison, WI).

Screening of MARC-145 cDNA library for simian vimentin. The cDNA library from MARC-145 cells was previously constructed in our laboratory in the λ ZAP express vector system (36). The cDNA library was screened by Southern blotting. The cDNA library was combined with Escherichia coli host strain K802, mixed with NZY agarose, and then poured onto NYZ agar plates. After being incubated at 37°C for 8 h, the plagues were transferred onto nylon membranes, denatured, neutralized, and fixed at 80°C for 2 h. The porcine vimentin cDNA from ST cells was used as a probe. The cDNA was labeled with [α-32P]dCTP by Ready-To-Go DNA-labeling beads (Amersham Biosciences Corp., Piscataway, NJ). The hybridization was performed at 73°C in hybridization solution (5% NaCl-EDTA-Tris-HCl buffer (SET), 5× Denhardt’s reagent, 1% SDS, 200 μg/ml denatured salmon sperm DNA, and 200 μg/ml heparin). The nylon membranes were washed for 30 min twice with wash buffer I (2× SET and 5× Denhardt’s reagent), for 30 min four times with wash buffer II (2× SET and 0.5% SDS), and for 30 min twice with wash buffer III (0.1× SET and 0.1% SDS). The nylon membranes were incubated with FITC-conjugated goat anti-rabbit IgG (H+L) (Bethyl Laboratories, Inc., Montgomery, TX) on ice for 30 min. After being washed twice with PBS, the membranes were incubated with FITC-conjugated monoclonal anti-vimentin (V9) Ab (Santa Cruz Biotechnology, Inc., Santa Cruz, CA) at 37°C for 30 min, washed twice with PBS, and then examined by fluorescence microscopy.

Flow cytometric analysis. MARC-145 cells (5×10^6 cells) were washed in staining solution (0.1% bovine serum albumin and 0.1% NaN₃ in PBS), blocked in 3% normal goat serum in staining solution on ice for 10 min, and then incubated with polyclonal rabbit anti-vimentin Ab (Biomedia, Foster City, CA) on ice for 30 min. After being washed twice with staining solution, the cells were incubated with FITC-conjugated goat anti-rabbit IgG (H+L) (Bethyl Laboratories, Inc., Montgomery, TX) on ice for 30 min. After being washed twice with staining solution, the cells were resuspended in 1% paraformaldehyde in PBS.

Flow cytometric analysis was performed on a FACS Calibur (BD Biosciences, San Jose, CA).

Generation of simian recombinant vimentin. Simian recombinant vimentin protein was produced in the QIAGEN expression system (QIAGEN, Valencia, CA). The full length of simian vimentin cDNA was digested with KpnI and BamHI, and then ligation was performed with KpnI- and BamHI-digested pQE-30 vector. The ligation-reaction mixture was transformed into competent M15 E. coli. After the expression of recombinant vimentin was induced by IPTG (isopropyl-β-D-thiogalactopyranoside) at a final concentration of 1 mM, recombinant vimentin was purified by Ni-nitrilotriacetic acid columns (QIAGEN, Valencia, CA).

Delivery of recombinant simian vimentin into PRRSV-nonsusceptible cells. Recombinant simian vimentin was delivered into BHK-21 and CRFK cells by the Chariot protein delivery system (Active Motif, Inc., Carlsbad, CA). BHK-21 and CRFK cells were cultured overnight in a 48-well tissue culture plate (5×10⁴ cells/well) and then fixed in cold 80% acetone at 4°C for 10 min. The cells were incubated with FITC-conjugated monoclonal anti-vimentin (V9) Ab (Santa Cruz Biotechnology, Inc., Santa Cruz, CA) at 37°C for 30 min, washed twice with PBS, and then examined by fluorescence microscopy.

Species-specific PRRSV-blocking monoclonal antibody 691

RESULTS

Production and characterization of PRRSV blocking MAb (7G10) and effect of 7G10 MAb on PRRSV infection. Production of the 7G10 MAb used, which blocks the infection of MARC-145 cells by PRRSV, was described in Materials and Methods. To study the effect of the 7G10 MAb on PRRSV infection, a plaque reduction assay was performed. The 7G10 MAb reduced the plaque titer by 98%.

Identification of 7G10 MAb-bound host cell protein complex. To capture 7G10 MAb-bound host cell proteins, an immunoaffinity column was prepared with 7G10 MAb. The protein complex retained on the 7G10 MAb affinity column was separated by 2-D electrophoresis, and five proteins were identified among the seven proteins (Fig. 1). All proteins were identified as cytoskeletal filaments. Protein spot (PS) 1 was vimentin, PS 3 was cytokeratin 8, PS 5 was keratin 18, PS 6 was actin, and PS 7 was hair type II basic keratin. The protein spots were cored and identified by MALDI-TOF MS (PS 101, vimentin; PS 102, no identification; PS 103, cytokeratin 8; PS 104, no identification; PS 105, keratin 18; PS 106, actin; PS 107, hair type II basic keratin).

Characterization of PRRSV-binding activity of vimentin. To examine whether vimentin, one of the 7G10 MAb-bound host cell proteins, could interact with PRRSV, VOPBA was performed. PRRSV was purified by polyethylene glycol precipitation, followed by a sucrose density gradient separation. The density of the purified PRRSV was 1.15 g/cm³. As shown in Fig. 2, the purified PRRSV bound to a 57-kDa band of vimentin, which was detected with SR-30, a MAb against PRRSV.
nucleocapsid protein (lane 1), while no band was observed in the negative control, which was identical except that no virus was added under the same conditions (lane 2). Binding of PRRSV to the 57-kDa band of vimentin was also detected with polyclonal Ab against PRRSV (data not shown).

Blocking activity of anti-vimentin Ab on PRRSV infection of MARC-145 cells. To investigate whether anti-vimentin Ab can block PRRSV infection of MARC-145 cells, a checkerboard titration assay was used. As shown in Table 1, PRRSV infection was blocked by polyclonal anti-vimentin Ab in a dose-dependent manner. At the low concentration of the virus (from $10^{-5}$ to $10^{-7}$ dilution), polyclonal anti-vimentin Ab showed a strong blocking effect, and the effect was dose dependent. At the high concentration of the virus (from $10^{-1}$ to $10^{-3}$ dilution), the Ab showed a weaker blocking effect. The concentration of $10^{-5}$-diluted Ab showed the best blocking effect against PRRSV infection, even at the high concentration of the virus ($10^{-1}$ or $10^{-2}$ dilution). However, an irrelevant Ab, anti-β-galactosidase MAb, did not block PRRSV infection.

Sequence analysis of the simian cDNA of vimentin from MARC-145 cells. The full-length cDNA of simian vimentin was screened in a MARC-145 cDNA library (GenBank accession number, DQ190949). As a probe, the partial cDNA of porcine vimentin was used, which was amplified by RT-PCR from ST cells (GenBank accession number, DQ190948). The simian vimentin cDNA sequence has the highest identity (97%) with the human vimentin sequence and also has high identity with the vimentin cDNA sequences of other species. Figure 3 shows the alignment of the simian vimentin amino acid sequence with human, bovine, murine, and porcine vimentin cDNA sequences. The simian vimentin amino acid sequence has the highest identity (99%) with the human vimentin amino acid sequence and also has high identity with the vimentin amino acid sequences of the other species. Nevertheless, the simian vimentin amino acid sequence has a few unique differences. The simian vimentin amino acid sequence has threonine residues at positions 2 (Thr-2) and 179 (Thr-179), while the other vimentin amino acid sequences have a serine residue at position 2 (Ser-2) and an alanine residue at position 179 (Ala-179).

Detection of vimentin by Western blot analysis. To examine the expression of vimentin in various cell lines, MARC-145, BHK-21, CRFK, MDCK, PK-15, ST, and Vero. Western blot analysis was performed using an anti-vimentin MAb (Fig. 4). In all cell lines, several bands were detected in a broad range, but the major bands were between 40 and 60 kDa. Interestingly, MARC-145 and Vero cells showed very similar patterns of vimentin bands.

Localization of vimentin in MARC-145 cells. To investigate the localization of vimentin in MARC-145 cells, immunofluorescence microscopy analysis was performed in permeabilized cells. Vimentin was found in the cytoplasm, especially concentrated around the plasma membrane (Fig. 5A). Next, we addressed whether vimentin is expressed on the cell surface. To examine the cell surface expression of vimentin, flow cytometric analysis was performed on nonpermeabilized MARC-145 cells. As shown in Fig. 5B, vimentin was expressed on the cell surface. We also examined the alteration of the cell surface expression of vimentin by PRRSV infection. The expression of vimentin on the cell surface was changed by PRRSV infection. At 2 days postinfection by PRRSV, the expression level of

<sup>a</sup>MARC-145 cells were cultured with PRRSV and/or anti-vimentin Ab in a 96-well tissue culture plate. Tenfold serial dilutions of the PRRSV preparation were prepared for reaction with serial two-fold dilutions of the polyclonal anti-vimentin Ab. After 3 days of incubation, immunofluorescence microscopy analysis was performed. The cells were fixed with 80% acetone and stained with FITC-conjugated SDOW-17, a MAb against PRRSV nucleocapsid protein. C, cytopathic effect; 0, no fluorescence detected; 1, low-intensity fluorescence; 2, medium-intensity fluorescence; 3, high-intensity fluorescence.
Vimentin was reduced to half compared to uninfected cells. However, the expression level of vimentin was restored to the same level as in uninfected cells at 3 days postinfection.

**Delivery of recombinant simian vimentin into nonsusceptible cells.** Recombinant protein was made from simian cDNA of vimentin in *E. coli* and then delivered into PRRSV-nonsusceptible cell lines, BHK-21 and CRFK. The β-galactosidase protein was used as a control in exactly the same way as vimentin. Figure 6A shows immunofluorescence microscopy analysis to detect PRRSV in the simian-vimentin recipient BHK-21 and CRFK cells. Both simian-vimentin recipient BHK-21 (a) and CRFK (c) cells were rendered susceptible to PRRSV, while β-galactosidase recipient BHK-21 (b) and CRFK (d) cells were still nonsusceptible to PRRSV. Figure 6B shows a sensitive RT-PCR assay to demonstrate PRRSV RNA production in the simian-vimentin recipient BHK-21 and CRFK cells. Simian vimentin was delivered into the BHK-21 and CRFK cells, and then the cells were infected with PRRSV. PRRSV RNA was detected in both simian-vimentin recipient BHK-21 (lane 3) and CRFK (lane 5) cells, while PRRSV RNA was not detected in β-galactosidase recipient BHK-21 (lane 4) and CRFK (lane 6) cells.

**DISCUSSION**

PRRSV is endemic in most swine-producing areas of the world, except a few countries in Europe (4) and Oceania (19). To decrease economic losses from PRRSV, effectively controlling the virus is one of the most important tasks. In many viruses, the viral receptors have been one of the targets for control of viral infection. PRRSV infects well-differentiated cells of the monocyte/macrophage lineage and cells derived
from African green monkey kidney cells by receptor-mediated endocytosis (13, 23, 25). So far, two putative receptors have been reported on primary macrophages: HS and Sn. Both HS and Sn are expressed only on PAM, not MARC-145 cells, which are widely used for virus isolation in vitro (10, 11, 12, 39). In this study, we identified the components of PRRSV blocking MAb (7G10)-bound complex. The complex was composed of vimentin and known vimentin-bound proteins; cytokeratin 8, cytokeratin 18, actin, and hair type II basic keratin. We also demonstrated that PRRSV bound to vimentin.

Vimentin is the most abundant component of IFs, which comprise cytoskeleton networks with microfilaments and microtubules. IFs are divided into five different types: types I, II, III, IV, and V. Vimentin is included in type III IFs with desmin, glial fibrillary acidic protein, and peripherin (16). Vimentin is widely expressed in various cell types, such as monocytes, macrophages, multinuclear giant cells, white blood cells, astrocytes, mesenchymal cells, muscle cells, and some neurons (3). Previous studies have reported that vimentin is localized in the cytoplasm, the perinuclear region, the Golgi apparatus, and the endoplasmic reticulum (3, 17, 29). It has also been demonstrated that vimentin is expressed on the cell surface and even secreted into the extracellular environment by activated macrophages (29). In this study, the cellular distribution of vimentin in MARC-145 cells was examined. Vimentin was localized on the cell surface, as well as in the cytoplasm, of MARC-145 cells as previously reported in other cells, such as monocytes and macrophages (29). Based on our findings, we propose that PRRSV binds to vimentin expressed on the surfaces of MARC-145 cells. Interestingly, the expression level of vimentin on the cell surface was modulated by PRRSV infection. Modulation of vimentin on the cell surface after PRRSV infection may occur due to binding of the PRRSV with the receptor, leading to opsonization and endocytosis of PRRSV. After 3 days postinfection, the expression level of vimentin returned to the preinfection level due to recovery of the cells. Delivery of simian vimentin into PRRSV-nonsusceptible cell lines, BHK-21 and CRFK, also supports the notion that vimentin might be a receptor of PRRSV. Both simian-vimentin recipient BHK-21 and CRFK cells were rendered susceptible to PRRSV infection. Both BHK-21 and CRFK cells normally lack PRRSV-binding activity (24).

Vimentin plays an important role in stabilizing the architecture of the cytoplasm in various cells. Additionally, vimentin and the other cytoskeletal filaments play important roles in virus entry and/or infection for many viruses, such as human immunodeficiency virus type 1 (22, 28, 37), Junin virus (9), human cytomegalovirus (1), vaccinia virus (34), Theiler’s murine encephalomyelitis virus (31), Epstein-Barr virus (35), adenovirus type 2 (2), human T-cell leukemia virus type I (27), influenza A virus (40), frog virus 3 (30), African swine fever virus (5), human respiratory syncytial virus (18), hemagglutinating virus of Japan (20), bluetongue virus (14), and herpes simplex virus type 1 (32). Especially in human immunodeficiency virus type 1 infection of differentiated macrophages and activated T lymphocytes, vimentin binds to the third hypervariable region (the V3 loop) of the viral envelope protein gp120.
FIG. 6. Delivery of simian vimentin into PRRSV-non-susceptible cell lines. (A) Simian recombinant vimentin or β-galactosidase was delivered into BHK-21 cells (a and b) and CRFK cells (c and d) in the Chariot protein delivery system. Simian vimentin or β-galactosidase recipient cells were infected with PRRSV. The cells were fixed with 80% acetone and stained with FITC-conjugated SDOW-17, a MAb against PRRSV nucleocapsid protein. The cells were examined by fluorescence microscopy and photographed at ×20. (B) A sensitive RT-PCR assay was performed to demonstrate the PRRSV RNA production in simian-vimentin or β-galactosidase recipient cells. M, DNA marker; lane 1, PRRSV-infected MARC-145; lane 2, PRRSV-uninfected MARC-145; lane 3, PRRSV-infected, vimentin recipient BHK-21; lane 4, PRRSV-infected, β-galactosidase recipient BHK-21; lane 5, PRRSV-infected, vimentin recipient CRFK; lane 6, PRRSV-infected, β-galactosidase recipient CRFK.

and subsequently induces the entry of the virus and translocation of the viral DNA (37).

Multifunctional proteins are often regulated by posttranslational modifications. Vimentin is one of the most prominent phosphoproteins in various cells and is phosphorylated by a variety of protein kinases (15, 38). The phosphorylation of vimentin may affect the properties of vimentin. For example, a previous study reported that vimentin was secreted into the extracellular space through the Golgi apparatus by phosphorylation, and the secreted vimentin might be related to the response to pathogens (29). In this study, vimentins from different cell lines were shown to migrate differently due to posttranslational modifications, such as phosphorylation. Interestingly, two PRRSV-susceptible cell lines, MARC-145 and Vero, show similar patterns of vimentin expression. Thus, phosphorylation of vimentin may be related to the restricted cell tropism of PRRSV. Also, a threonine residue which is present at position 2 (Thr-2) in the amino acid sequence of simian vimentin may determine the use of vimentin as a host range determinant for the simian cell line. The hydroxyl group of threonine is buried and offers less flexibility in contact with PRRSV. However, the hydroxyl group of serine (Ser-2) of vimentin in the other species is more exposed and makes general contact in a less specific manner. Thus, simian vimentin can function as a specific viral receptor, while vimentins in the other species lack a receptor function. The fact that very few amino acids are critical in virus-receptor interaction has been reported in several viruses. It has been recently reported that the difference of 4 amino acids in the receptor-binding domain of the human epidemic strain of severe acute respiratory syndrome coronavirus (SARS-CoV) causes more than a 1,000-fold difference in binding affinity to its receptor, human angiotensin-converting enzyme 2 (ACE2). Especially, the change of an amino acid residue at position 487 (serine to threonine) of the spike proteins between civet and human virus strains is strongly related to the adaptation of SARS-CoV to humans (21). Also, in its receptor, highly conserved among mammals, few amino acids are critical in virus-receptor binding activity. Human ACE2 has a lysine at position 353 (Lys-353) that is critical for the interaction with Thr-487 in the receptor binding domain of SARS-CoV. However, rat and mouse ACE2, which inefficiently support infection by SARS-CoV, have a histidine at position 353 (His-353). Replacement of His-353 with lysine in mouse ACE2 allows high-level infection of murine cells (26).

In the present study, it was shown that PRRSV bound to vimentin, and PRRSV infection of MARC-145 cells was blocked by anti-vimentin Abs. In MARC-145 cells, vimentin was expressed on the cell surface, as well as in the cytoplasm, and associated with the other cytoskeletal filaments in the cytoplasm. Here, we report that vimentin may be a putative receptor of PRRSV and may play an important role with the other cytoskeletal filaments in PRRSV infection. To our knowledge, this is the first demonstration of the interaction of PRRSV with cytoskeletal filaments, such as vimentin.
