Received 12 November 2007/Accepted 29 February 2008

We have constructed a recombinant herpes simplex virus type 1 (HSV-1) that simultaneously encodes selected structural proteins from all three virion compartments—capsid, tegument, and envelope—fused with autofluorescent proteins. This triple-fluorescent recombinant, rHSV-RCY, was replication competent, albeit with delayed kinetics, incorporated the fusion proteins into all three virion compartments, and was comparable to wild-type HSV-1 at the ultrastructural level. The VP26 capsid fusion protein (monomeric red fluorescent protein [mRFP]-VP26) was first observed throughout the nucleus and later accumulated in viral replication compartments. In the course of infection, mRFP-VP26 formed small foci in the periphery of the replication compartments that expanded and coalesced over time into much larger foci. The envelope glycoprotein H (gH) fusion protein (enhanced yellow fluorescent protein [EYFP]-gH) was first observed accumulating in a vesicular pattern in the cytoplasm and was then incorporated primarily into the nuclear membrane. The VP16 tegument fusion protein (VP16-enhanced cyan fluorescent protein [ECFP]) was first observed in a diffuse nuclear pattern and then accumulated in viral replication compartments. In addition, it also formed small foci in the periphery of the replication compartments which, however, did not colocalize with the small mRFP-VP26 foci. Later, VP16-ECFP was redistributed out of the nucleus into the cytoplasm, where it accumulated in vesicular foci and in perinuclear clusters reminiscent of the Golgi apparatus. Late in infection, mRFP-VP26, EYFP-gH, and VP16-ECFP were found colocalizing in dots at the plasma membrane, possibly representing mature progeny virus. In summary, this study provides new insights into the dynamics of compartmentalization and interaction among capsid, tegument, and envelope proteins. Similar strategies can also be applied to assess other dynamic events in the virus life cycle, such as entry and trafficking.

and to copurify with UL47 (67) and with VP22 (16). Due to its involvement in linking capsid and future envelope-associated tegument proteins during virion formation, VP16 is absolutely required for assembly of infectious virus (63) and plays essential roles in viral maturation and egress (24, 44).

The tegument is surrounded by the viral envelope, which is a lipid membrane of cellular origin that contains at least 11 different viral glycoproteins. The glycoproteins are the major antigenic determinants for the host-specific recognition, and they are involved in cell entry, cell-to-cell spread, and immune evasion. Glycoprotein H, the product of the UL22 gene, is a 110-kDa protein which is essential for infectivity (14) and membrane fusion, but not for receptor binding (22, 25). Glycoprotein H must be coexpressed with gL in order for both proteins to be properly processed, folded, and transported to the virion envelope as well as the infected cell surface (33). The gH/gL complex plays essential roles in viral penetration, cell-to-cell spread, and syncytium formation (53). Both glycoproteins are conserved among the herpesviruses, although some differences regarding assembly, structure, and intracellular transport of the heterocomplex exist between individual herpesviruses (27, 33, 34, 50). Only very recently was it shown that the simultaneous deletion of gH and gB alone did not lead to a significant defect (19). One strategy to investigate mechanisms of viral infection, replication, and assembly is the fusion of viral proteins with autofluorescent proteins (reviewed in reference 5). Many of the HSV-1 proteins have been shown to maintain their functional activity when fused with foreign polypeptides. Among these, a green fluorescent protein (GFP)-VP26 fusion was demonstrated to be incorporated into intranuclear capsids and mature virions, where it was capable of interacting with VP5 while retaining its autofluorescence (13). GFP-VP26 retained its biological activity during the replication cycle, as the recombinant virus replicated at a rate comparable to that of wild-type (wt) virus (13).

A recombinant HSV-1 that expressed VP16 fused to GFP (VP16-GFP) also showed normal replication kinetics and incorporation of the fusion protein into the virion (35). Similarly, fusion of enhanced yellow fluorescent protein (EYFP) with gH did not markedly alter gH functions, as the recombinant virus was replication competent and showed stable autofluorescence (39). The EYFP-gH fusion protein formed a stable heterocomplex with gL and was incorporated into the virion envelope as well as cellular membranes (39).

In this study, we have constructed a recombinant HSV-1 that simultaneously encodes the VP26 capsid protein fused with monomeric red fluorescent protein (mRFP), the VP16 tegument protein fused with enhanced cyan fluorescent protein (ECFP), and the gH envelope glycoprotein fused with EYFP. This triple-fluorescent recombinant HSV-1, rHSV-RYC, was replication competent and incorporated the autofluorescent fusion proteins into all three virion compartments. Confocal laser scanning microscopy (CLSM) of living infected cells revealed new insights into the organization and dynamics of HSV-1 infection and into the interactions between HSV-1 virion proteins. To our knowledge this is the first report of the construction and live analysis of a recombinant virus encoding three different autofluorescent fusion proteins.
to the TACAGCTCGTCCATGCCGAG-3′. Sequence portions shown in italics are homologous to the galK gene. The following plasmids (10 ng) were used as templates: pgalk for all galK selection/targeting cassettes (obtained from S. Warming, National Cancer Institute, Frederick, MD) (62), pcDNA-mRFP-N1 (obtained from U. F. Greber, University of Zurich, Zurich, Switzerland) for the VP26-mRFP targeting cassette, and pECPF-N1 and pEYPF-N1 for amplification of VP16-ECFP/EFYP and gh-EYFP targeting cassettes, respectively. The PCR conditions were as follows: 94°C for 15 s, 60°C for 30 s, and 72°C for 1 min, for 30 cycles. After completion of the reaction, DpnI (10 U; New England Biolabs, Alphaw, Switzerland) was added for digestion of the template for 2 h. The DpnI-digested reaction mix was run on 1% agarose gel, and the PCR product was purified using a QIAquick PCR purification kit (Invitrogen). After 2 to 3 days of incubation at 37°C, the supernatant was harvested and plaque purified twice, and the excision of the BAC sequences was verified by PCR.

**Excision of BAC sequences and isolation of recombinant HSV-1**

To excise the BAC DNA backbone and isolate recombinant viruses, 1.2 × 107 Vero 2-2 cells (56) per 6-cm tissue culture plate were cotransfected with 0.2 μg of plasmid p116, which expresses Cre recombinase with an NLS (kindly provided by K. Tobler, University of Zurich, Zurich, Switzerland), and 2 μg of Ctsi gradient-purified recombinant HSV-1 BAC DNA using Lipofectamine (Invitrogen). After 2 h of incubation at 37°C, the cultures were frozen and thawed, followed by centrifugation at 1,900 g.

**Determination of particle/PFU ratios.** To determine the particle counts, virus stocks with known titers (PFU/ml) were mixed with 204-mm-diameter latex beads (Agar Scientific, Essex, United Kingdom) of known concentration, adsorbed onto 300-mesh parlodion- and carbon-coated copper electron microscope grids for 5 min at room temperature (RT), briefly washed with H2O, and negatively stained with 2% sodium phosphotungstate, pH 7.4, for 1 min at RT. Samples were examined in a transmission electron microscope (CM12; Philips, Eindhoven, The Netherlands), and the relative numbers of virus particles and latex beads were determined, which allowed us to calculate the absolute numbers of virus particles in the virus stocks.

**Purification of virions.** Virions were purified from BHK or Vero cells infected at an MOI of 0.1 PFU with either wt HSV-1, rHSV-RY, or rHSV-RYC/2. When the cytopathic effect (CPE) was complete, the cultures were frozen and thawed three times, and the cell debris was removed by centrifugation for 10 min at 2,600 × g and 4°C. Virions were purified through 60%, 30%, and 10% sucrose (in PBS) gradients in Beckman Ultra-Clear 25- by 89-mm centrifuge tubes, which were centrifuged for 2 h at 28,000 rpm and 4°C using a Beckman SW28 rotor. The interface between the 30% and 60% sucrose layers was collected, diluted in PBS, and ultracentrifuged for 1 h at 25,000 rpm and 4°C. Following resuspension of the pellet in Hanks’ buffered saline solution, the virion stocks were frozen in a dry ice-ethanol bath and stored at −80°C.

**Immunoprecipitation, SDS-PAGE, Western analysis, and silver staining.** Vero cells (4 × 105 cells per well in a 12-well plate) were mock infected or infected with either wt HSV-1, rHSV-RY, rHSV-RYC, or rHSV-RYC/2 at an MOI of 1 PFU. When CPE was almost complete (between 24 and 48 h postinfection [p.i.]), the cells were washed with cold PBS and prepared for immunoprecipitation or directly lysed with sodium dodecyl sulfate (SDS) loading buffer, boiled for 5 min, and analyzed by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and Western blotting using the antibodies listed below. For immunoprecipitation, SDS-PAGE, Western analysis, and silver staining.
kindly provided by A. Minson and H. Browne, University of Cambridge, United Kingdom) (41), GFP (MAb JB-8D, diluted 1:8,000 in PBS-T; Clontech, Saint-Germain-en-Laye, France), ICPS (MAb, diluted 1:10,000 in PBS-T; Advanced Biotechnologies, Columbia, MD), ICPS (MAb clone 10A3, diluted 1:10,000 in PBS-T; Abcam, Cambridge, United Kingdom), and VP22 (rabbit PAB AVG031, diluted 1:10,000 in PBS-T; kindly provided by G. Elliott, Marie Curie Research Institute, Orsted, United Kingdom). After washing, the membranes were incubated with rabbit anti-mouse immunoglobulin G (IgG)-horseradish peroxidase (HRP) (1:10,000 in PBS-T; Sigma-Aldrich, Buchs, Switzerland) or goat anti-rabbit IgG–HRP (1:10,000 in PBS-T; Sigma-Aldrich, Buchs, Switzerland). Target proteins were visualized by enhanced chemiluminescence (ECL Western blotting analysis system; GE Healthcare, Zurich, Switzerland) and autoradiography (Lumi-film chemiluminescent detection film; Roche Diagnostics, Rotkreuz, Switzerland). A molecular weight standard (BenchMark prestained ladder; Gibco, Invitrogen, Basel, Switzerland) was used to determine the sizes of the protein bands. Silver staining of gels was performed using the Bio-Rad silver stain kit (Bio-Rad, Hercules, CA) according to the manufacturer’s manual.

CLSM. CLSM was performed on a Leica TCS SP2 AOBS confocal laser scanning microscope (Leica Microsystems, Wetzlar, Germany) equipped with an incubation chamber (THE BOX; Live Imaging Services, Reinach, Switzerland), a temperature control device (THE CUBE; Live Imaging Services, Reinach, Switzerland), and a gas mixer (THE BRICK; Live Imaging Services, Reinach, Switzerland). The settings for the individual fluorophores were as follows: 4′,6-diamidino-2′-phenylindole (DAPI), excitation at 405 nm and recording at 415 to 480 nm; ECFP, excitation at 458 nm and recording at 468 to 510 nm; fluorescein isothiocyanate (FITC), excitation at 488 nm and recording at 498 to 570 nm; EYFP, excitation at 514 nm and recording at 520 to 550 nm; mRFP/Atto590/AF590, excitation at 550 nm and recording at 560 to 600 nm. In order to avoid channel overlap, blue and red channels were recorded simultaneously while the yellow/green channels were recorded separately. The images shown in Fig. 7 and 8, below, were deconvolved with a blind deconvolution algorithm using the Huygens Essential 2.6.0p1 software (Scientific Volume Imaging, Hilversum, The Netherlands). Image processing was done with Imaris 5.0.1 (Bitplane AG, Zurich, Switzerland) and Adobe Photoshop CS 8.0.1 software.

(i) High-resolution CLSM of live or fixed, infected cells. Vero cells were seeded on Lab-Tek four-well chambered coverglasses (Nalge Nunc International, Rochester, NY) at 105 cells/well. On the following day, the cells were washed once with cold (4°C) DMEM and incubated for 15 min at 4°C, and the DMEM was replaced with cold (4°C) virus inoculum at the MOIs described in the figure legends. The viruses were then allowed to adsorb to the cells for 1 h at 4°C with gentle shaking. Subsequently, the virus inoculum was replaced with warm (37°C) Iscove’s modified Dulbecco’s medium (Gibco, Invitrogen, Basel, Switzerland) supplemented with 25 mM HEPES and 2% FBS, and the cells were incubated at 37°C, 5% CO2. At the indicated times after infection (temperature shift), live cells were observed by CLSM in a humid atmosphere at 37°C, 5% CO2. Where mentioned in the text below, the cells were fixed with 3.7% formaldehyde in PBS for 15 min at RT prior to electron microscopy.

(ii) Time-lapse CLSM of live, infected cells. Vero cells were seeded into 35-mm glass bottom dishes (MatTek, Ashland, MA) at 5 × 104 cells/dish. On the following day, the cells were infected with hHSV-RY or hHSV-RY diluted in DMEM at the MOIs described in the text below. The viruses were allowed to adsorb for 1 h at 37°C, 5% CO2. The cells were then washed with PBS, overlaid with Iscove’s modified Dulbecco’s medium supplemented with 25 mM HEPES and 2% FBS, and incubated at 37°C, 5% CO2. At the indicated time points, the cells were washed once with cold PBS and fixed with 3.7% formaldehyde in PBS for 15 min at RT, and the fixation was stopped with 0.1 M glycine in PBS for 5 min at RT. Immunofluorescence staining, DAPI staining, and embedding of cells were performed as described previously (29) except that the cells were permeabilized with 0.2% Triton X-100 in PBS for 15 min at RT and 0.2% Triton X-100, 1% Tween 20 (sigma) (Sigma-Aldrich, Buchs, Switzerland) was included in the blocking solution when cells were stained with antibodies of rabbit origin. Primary antibodies were used at the following dilutions: anti-hHSV-1 ICPS MAB J781 (kindly provided by R. D. Everett, MRC Virology Unit, Glasgow, United Kingdom) 1:500 (see Fig. 6C, below) or 1:1,000 (see Fig. 6D, below); anti-hHSV-1 gH MAb LP11, 1:3; anti-hHSV-1 VP16 MAb LP1, 1:3 (see Fig. 8A, below) or 1:200 (see Fig. 8D, below); rabbit anti-hHSV-1 VP26 PAB VP26/C (kindly provided by P. Desai, Johns Hopkins University, Baltimore, MD) (12), 1:400. Secondary antibodies were used as follows: F(ab′)2 fragment of goat anti-rabbit IgG(H + L)+AF594 (Molecular Probes, Invitrogen, Basel, Switzerland), 1:200; goat anti-rabbit IgG(H+L)+FITC (Southern Biotechnology, Birmingham, AL), 1:100; goat anti-mouse IgG(H+L)+AF594 (Molecular Probes, Invitrogen, Basel, Switzerland), 1:200; Fab fragment of goat anti-mouse IgG(H+L)+-FITC (Jackson ImmunoResearch, West Grove, PA), 1:100.

FISH. Infection with wt HSV-1 and immunofluorescence staining for VP26 were performed as described above. Fluorescent in situ hybridization (FISH) was performed as described previously (18) with the following modifications: (i) cells were fixed with precooled methanol for 10 min at −20°C; (ii) immunofluorescence staining was performed before the hybridization step; (iii) fluorescent labeling of BAC-cloned HSV-1 DNA (YBac102) was performed with an Atto590 nick translation labeling kit according to the manufacturer’s manual (Jena Bioscience, Jena, Germany).

Electron microscopy. Vero cells were grown on sapphire disks for 2 days prior to infection with hHSV-RY. After 24 h, cells were fixed with 0.5% glutaraldehyde for 30 min and then frozen in a high-pressure freezer (HM2000; BAL-TEC Inc., Balzers, Liechtenstein) or a cryomicrotome at −60°C for 1 to 2 h. The cells were then thawed, rehydrated, and postfixed in 1% osmium tetroxide in 0.1 M sodium cacodylate buffer pH 7.4 for 1 h, washed in distilled water, embedded in Epon, and polymerized at 60°C for 3 days prior to Sectioning.

RESULTS

Construction of a recombinant HSV-1 encoding mRFP-VP26, VP16-ECFP, and EYFP-gH fusion proteins. The goal of this study was to construct and characterize a recombinant HSV-1 that simultaneously encodes selected structural proteins from all three virion compartments fused with autofluorescent proteins, in particular, capsid protein VP26 fused with mRFP, tegument protein VP16 fused with ECFP, and envelope glycoprotein H fused with EYFP. This triple-fluorescent recombinant HSV-1 was constructed via homologous recombination in E. coli using a BAC-cloned HSV-1 strain F genome (pYBac102) (59) and the galK positive/negative selection method (62) as described in Materials and Methods. Briefly, in a first step, a DNA fragment containing the galK expression cassette flanked by homology arms that target the cassette between codons 1 and 5 of the VP26 coding sequences was electroporated into E. coli SW102 cells that contained the pYBac102 HSV-1 BAC DNA. Gal-positive recombinant bacteria were selected on galactose minimal medium plates. BAC DNA prepared from these clones was characterized by restriction endonuclease analysis (not shown), and one clone (rHSVBAc35galK) was selected for the second recombination step. For the second step, the galK expression cassette was replaced by electroporating a DNA fragment containing the mRFP expression cassette, again flanked by the homology arms that facilitate the in-frame insertion of mRFP coding sequences between codons 1 and 5 of the VP26 coding sequences, into E. coli SW102/rHSVBAc35galK. After galK counterselection with DOG, Gal-negative colonies were picked, BAC DNA was prepared and characterized by restriction endonuclease analysis (not shown), and one clone (rHSVBAc35R1; Fig. 1A) was selected for further manipulation. The subsequent fusion of gH with EYFP (rHSVBAc35R22Y; Fig. 1B) and VP16 with ECFP (rHSVBAc35R22Y48C; Fig. 1C...
was performed using the same *galK* positive/negative selection procedure described above and in Materials and Methods. The final recombinant, rHSV-BAC35R22Y48C, contained codons 1 to 225 of mRFP fused to codons 5 to 108 of VP26, codons 2 to 239 of EYFP inserted between codons 6 and 9 of gH, and codons 1 to 489 of VP16 fused to codons 2 to 239 of ECFP. Two additional recombinant HSV-1 BACs were constructed that contained either codons 1 to 489 of VP16 fused to codons 2 to 239 of EYFP (rHSV-BAC48Y) or codons 1 to 225 of mRFP fused to codons 5 to 108 of VP26 and codons 1 to 489 of VP16 fused to codons 2 to 239 of ECFP (rHSV-BAC35R22Y48C). A second triple-fluorescent recombinant HSV BAC, rHSV-BAC35R22Y48C/2, was created by introducing codons 2 to 239 of EYFP between codons 6 and 9 of gH in rHSV-BAC35R48C. The two triple-fluorescent HSV BACs, rHSV-BAC35R22Y48C and rHSV-BAC35R22Y48C/2, encode the same fusion proteins, but these were inserted in different orders. To confirm that the recombinations had occurred as expected, BAC DNA was analyzed by restriction endonuclease digestion and Southern blot analysis (not shown). Finally, to rescue recombinant viruses and release the virus genome from the BAC backbone, recombinant HSV-1 BAC DNA was cotransfected with a Cre recombinase-expressing plasmid, p116, into mammalian cells (Fig. 1). Progeny virus was harvested after 2 to 3 days and plaque purified twice, and the excision of the BAC sequences was confirmed by PCR analysis (not shown). The recombinant viruses constructed and used in this study were designated as follows: rHSV-R (mRFP-VP26), rHSV-48Y (VP16-EYFP), rHSV-RY (mRFP-VP26 and EYFP-gH), rHSV-RC (mRFP-VP26 and VP16-ECFP), rHSV-RYC (mRFP-VP26, EYFP-gH, and VP16-ECFP), and rHSV-RYC/2 (mRFP-VP26, EYFP-gH, and VP16-ECFP). The two triple-fluorescent recombinants, rHSV-RYC and rHSV-RYC/2, produced comparable titers and showed identical patterns of fluorescence in infected cells (not shown).

**Synthesis of autofluorescent fusion proteins in infected cells.** To verify that the recombinant viruses expressed the fluorescent fusion proteins, Vero cells were mock infected or infected with either wt HSV-1 (wt), rHSV-RY (RY), or rHSV-RYC (RYC) at an MOI of 1 PFU and harvested when the CPE was approximately 90%. Cell lysates were analyzed by SDS-PAGE followed by Western blotting with antibodies against VP26 (A), VP16 (B), GFP (C), ICP4 (F), and ICP8 (G). For detection of gH and EYFP-gH, cell lysates were immunoprecipitated with a gH-specific antibody followed by SDS-PAGE and silver staining (D) or Western blotting with a GFP-specific antibody (E). Arrows indicate the mRFP-VP26, VP16-ECFP, and EYFP-gH fusion proteins, as well as the wt VP26, VP16, gH, ICP4, and ICP8 proteins. The arrowheads in panels D and E point to a band that likely represents the EYFP-gH precursor. Sizes of molecular weight standards are indicated.

**FIG. 2.** Expression of fluorescent fusion proteins in infected cells. Vero cells were mock infected (m) or infected with either wt HSV-1 (wt), rHSV-RY (RY), or rHSV-RYC (RYC) at an MOI of 1 PFU and harvested when the CPE was approximately 90%. Cell lysates were analyzed by SDS-PAGE followed by Western blotting with antibodies against VP26 (A), VP16 (B), GFP (C), ICP4 (F), and ICP8 (G). For detection of gH and EYFP-gH, cell lysates were immunoprecipitated with a gH-specific antibody followed by SDS-PAGE and silver staining (D) or Western blotting with a GFP-specific antibody (E). Arrows indicate the mRFP-VP26, VP16-ECFP, and EYFP-gH fusion proteins, as well as the wt VP26, VP16, gH, ICP4, and ICP8 proteins. The arrowheads in panels D and E point to a band that likely represents the EYFP-gH precursor. Sizes of molecular weight standards are indicated.
The band intensity of the wt 12-kDa VP26 protein was consistently weaker than that of the 50-kDa mRFP-VP26 fusion protein. The reason for this might be that the relatively small VP26 protein adsorbed less well to the nitrocellulose membrane than the larger fusion protein.

Western blotting with the anti-VP16 MAb LP1 (41) detected the VP16 protein in lysates of cells infected with either wt HSV-1 or rHSV-RY. In rHSV-RCY-infected cell lysates, however, the native VP16 was replaced by a band of approximately 100 kDa, which was also detected by the GFP-specific MAb JL-8BD (Fig. 2B and C). As the GFP-specific antibody reacts not only with GFP and ECFP but also with EYFP, a band of approximately 140 kDa was visible in both rHSV-RY- and rHSV-RCY-infected cell lysates which represented the EYFP-gH fusion protein (Fig. 2C, left panel). Of note is that the levels of the EYFP-gH fusion protein appeared to be higher in rHSV-RY- than in rHSV-RCY-infected cells. We therefore compared the EYFP-gH expression level of rHSV-RCY to that of the independently constructed triple-labeled virus, rHSV-RCY/2, as well as to rHSV-RY. As shown in Fig. 2C (right panel), the ratios between EYFP-gH and VP16-ECFP were comparable for both triple-labeled viruses. In addition, in this experiment, the total amounts of EYFP-gH appeared similar for the double- and triple-labeled viruses. The reason for the fairly low levels of EYFP-gH detected in some experiments therefore appears to be due to variations in the efficiency of infection between different experiments, rather than due to an inherent inability of the triple-colored viruses to express normal amounts of EYFP-gH.

To compare the expression levels of gH from wt HSV-1 and those of EYFP-gH from the recombinant viruses, cell lysates were immunoprecipitated with the gH-specific MAb LP11 (6), which binds to a conformational epitope of gH, followed by SDS-PAGE and silver staining of the gel (Fig. 2D). A band corresponding to the molecular mass of gH (110 kDa) was visible for wt HSV-1 but was replaced with bands corresponding to the molecular mass of EYFP-gH (140 kDa) in the samples of the recombinant viruses. The levels of gH appeared to be higher for wt HSV-1 and for rHSV-RY than for rHSV-RCY. To confirm expression of the EYFP-gH fusion protein, lysates were first immunoprecipitated with the gH-specific MAb LP11 and then analyzed by SDS-PAGE and Western blotting. The GFP-specific antibody detected the approximately 140-kDa EYFP-gH fusion protein in both rHSV-RY- and rHSV-RCY-infected cell lysates (Fig. 2E). Of note is that the levels of EYFP-gH were similar in this setting. Interestingly, in rHSV-RY-infected cell lysates but not in rHSV-RCY-infected cell lysates, a slightly smaller band was also visible, which likely represents the EYFP-gH precursor (30) (Fig. 2E). The accumulation of the EYFP-gH precursor might be a consequence of the higher total levels of EYFP-gH of rHSV-RY resulting in incomplete processing of the precursor, while the lower EYFP-gH levels expressed by rHSV-RCY may be completely processed into the mature form. The GFP-specific antibody also detected the VP16-ECFP fusion protein in rHSV-RCY-infected and LP11-immunoprecipitated cell lysates (Fig. 2E), which is consistent with an earlier finding that gH can coimmunoprecipitate with VP16 (31). An alternative explanation, however, could be that VP16-ECFP and EYFP-gH coim-
kinetics of virion release, there was no clear correlation between the number of tagged virion proteins and the reduction in titer. Finally, the recombinant viruses did not seem to have a specific deficit at the level of virion egress, since the differences between the wt virus and the recombinants were comparable in the supernatant and the pellet. The data rather suggest that the kinetics of recombinant virus replication was delayed.

Incorporation of autofluorescent fusion proteins into the virion. To confirm that all three fusion proteins were incorporated into the virion, wt HSV-1 virions and rHSV-RYC virions were prepared by sucrose gradient centrifugation and analyzed for the presence of the recombinant proteins. Western blotting with the VP26-specific PAb revealed the 12-kDa VP26 in wt HSV-1 virions and the 50-kDa mRFP-VP26 fusion protein in rHSV-RYC virions (Fig. 4A). Similar to the observations made in Fig. 2A, the band intensity of the wt VP26 protein was weaker than that of the mRFP-VP26 fusion protein. As previously mentioned, this difference might be due to different efficiencies of adsorption to the nitrocellulose membrane, since it is unlikely that the fusion protein is incorporated more efficiently into the virions than the wt protein. Similar observations were also made in a previous report (45). In order to obtain a visible band for wt VP26, a doubled amount of wt virions was loaded for the blot shown in Fig. 4A. Western blotting with the VP16-specific MAb revealed the presence of VP16 in the wt virions and VP16-ECFP in the rHSV-RYC virions, the amounts of which appeared comparable (Fig. 4B). The VP16-ECFP fusion protein, but not wt VP16, could also be detected with the GFP-specific MAb (Fig. 4C). As expected, the anti-GFP MAb also detected the EYFP-gH fusion protein (Fig. 4C). As noted in Fig. 2, the ratio of EYFP-gH to VP16-ECFP was quite variable between individual experiments (Fig. 2C, compare left and right panels). To detect gH from wt HSV-1 and EYFP-gH from rHSV-RYC, virion proteins were immunoprecipitated with the gH-specific MAb LP11 followed by SDS-PAGE and silver staining. The results shown in Fig. 4D demonstrate the presence of gH in wt virions and EYFP-gH in rHSV-RYC virions. Again, it appeared that the level of gH was higher in the wt virus than in with the recombinant. As expected, immunoprecipitation of virion lysates with LP11 followed by Western blotting with the anti-GFP MAb detected the EYFP-gH fusion protein but not the wt gH (Fig. 4E). As previously noted (Fig. 2E), VP16-ECFP immunoprecipitated with EYFP-gH (Fig. 4E). Staining for the VP22 tegument protein confirmed that comparable amounts of virions were loaded on the gels (Fig. 4F). Taken together, these results demonstrate that all three fusion proteins, mRFP-VP26, VP16-ECFP, and EYFP-gH, are indeed incorporated into the virus particle, although the amounts of incorporated EYFP-gH were lower than those of wt gH.

Dynamics of compartmentalization of mRFP-VP26, VP16-ECFP, and EYFP-gH in infected cells. Next, we monitored the localization of mRFP-VP26, VP16-ECFP, and EYFP-gH in

![Figure 3. Growth kinetics of recombinant HSV-1 and wt HSV-1. Vero cells were infected with MOIs of 0.1 (A and B) or 5 (C and D) PFU of either a recombinant HSV-1 (rHSV-R, rHSV-RY, rHSV-RYC, rHSV-RC, or rHSV-48Y) or wt HSV-1, and progeny virus was harvested from the cell culture medium (A and C) or from the cells (B and D) at 0, 12, 24, 36, and 48 h p.i. Titers are expressed as PFU per ml. The titers represent means from three experiments. Error bars represent standard deviations.](http://jvi.asm.org/)

infected cells. For this, Vero cells were plated onto chambered coverglasses and infected with rHSV-RYC, and live cells were examined by CLSM at various times after infection. In the first hours postinfection, small fluorescent foci were detected on the surface of the cells and within the cytoplasm (Fig. 5a to d). Some foci show colocalizations of ECFP, EYFP, and mRFP signals, suggesting that they represent intact virions from the virus inoculum (Fig. 5a to d, insets). De novo protein synthesis was first observed at 6 h p.i. for VP16-ECFP, which was found diffusely in the nucleus with accumulation in very early viral replication compartments (RCs) (Fig. 5e and h). At 8 h p.i., VP16-ECFP was present in mature nuclear RCs as well as in the cytoplasm, where it was found in a diffuse pattern with accumulation in some small perinuclear foci (Fig. 5i and l). At this time, expression of EYFP-gH and mRFP-VP26 also became apparent. In particular, EYFP-gH was found diffusely in the cytoplasm with some accumulation in a vesicular pattern around the nucleus (Fig. 5j and l), while mRFP-VP26 was found in small microfoci which were distributed throughout the nucleus with accumulation in viral RCs (Fig. 5k and l).

These small microfoci displayed a high mobility within the nucleus (not shown), reflecting active movement of nuclear capsids (21). The localization of the VP26 and VP16 fusion proteins to RCs was confirmed by staining rHSV-R- and rHSV-48Y-infected cells for ICP8, a marker for RCs (Fig. 6C and D). Between 10 and 16 h p.i., VP16-ECFP was predominantly found in the viral RCs as well as in small foci in their periphery. In addition, the cytoplasmic VP16-ECFP accumulation became more intense, with a pronounced recruitment of VP16-ECFP to the plasma membrane, where it was found in a dot-like pattern (Fig. 5m and p). At this stage, EYFP-gH was still prominent in the cytoplasm but now strongly accumulated in the nuclear membrane (Fig. 5n and p). Microfoci of mRFP-VP26 were still observed in the cytoplasm but now strongly accumulated in the nuclear membrane (Fig. 5o and p). These large foci have previously been suggested to correspond to sites of capsid assembly, so-called assemblons (13). Between 18 and 24 h p.i., two additional patterns became apparent.

FIG. 5. High-resolution CLSM of living rHSV-RYC-infected cells. Vero cells were infected with an MOI of 18 PFU, and live cells were observed by CLSM with settings specific for ECFP (VP16-ECFP fusion protein), EYFP (EYFP-gH fusion protein), and mRFP (mRFP-VP26 fusion protein). The thin gray lines in panels a to d mark the contours of the nucleus. The insets in panels a to d show a magnification of the sector denoted by the white square. The filled arrowheads within the insets point to colocalizations of ECFP, EYFP, and mRFP signals. Arrows, early RCs; filled triangle, VP16-ECFP foci in periphery of RCs; open triangles, large mRFP-VP26 and VP16-ECFP foci in periphery of nuclei; filled diamonds, asymmetric, perinuclear accumulation of VP16-ECFP and mRFP-VP26. Images represent single z stacks of the cells.
First, the majority of the VP16-ECFP was consistently recruited out of the nucleus into the cytoplasm. Specifically, it was found accumulating in an asymmetric, perinuclear pattern reminiscent of the Golgi complex, where it often colocalized with mRFP-VP26 and associated with EYFP-gH (Fig. 5q to t). Second, in a subset of cells, VP16-ECFP was recruited into the large mRFP-VP26 foci in the periphery of the nucleus, while EYFP-gH remained in a pronounced perinuclear pattern (Fig.
Finally, at these late time points, the dot-like accumulations of VP16-ECFP at the plasma membrane consistently colocalized with EYFP-gH and mRFP-VP26 (Fig. 5q to t), suggesting that they reflect the accumulation of progeny virus at the plasma membrane. This possibility was further investigated by high-magnification CLSM of the plasma membrane, which, as previously described, often formed pronounced plasma membrane protrusions (35) (Fig. 6A and B). On such plasma membrane protrusions, we observed a very strong association of VP16-ECFP and mRFP-VP26 (Fig. 6A, panel d) as well as a somewhat looser association of EYFP-gH with mRFP-VP26 and VP16-ECFP (Fig. 6A, panels e and f). The looser association of EYFP-gH with mRFP-VP26 and VP16-ECFP is probably due to the fact that we observed living cells and that while the ECFP and the mRFP channels were recorded simultaneously, the EYFP channel was recorded separately, thus explaining the observed differences in the degree of colocalization. Indeed, the association between the three signals was more pronounced in fixed cells (Fig. 6B). These observations, together with the fact that the number of dots increased in the course of infection, support the hypothesis that the dot-like accumulation of virion proteins of three different compartments at the plasma membrane might correspond to accumulating virion progeny. Nevertheless, it cannot be excluded that at least a subset of these foci also represent virions from the inoculum which did not successfully enter the cell and thus remained bound to the plasma membrane.

In order to obtain a more detailed picture of the subnuclear...
distribution of the large mRFP-VP26 foci, we infected cells with rHSV-RY, fixed them at 16 or 20 h p.i., and stained the nuclei with DAPI. CLSM analysis revealed that, at such late time points, the large mRFP-VP26 foci were often located at the very periphery of the nuclei (Fig. 7A) and that the density of mRFP-VP26 within these large foci was not homogenous (Fig. 7B). Rather, mRFP-VP26 accumulated strongly at the rim and displayed only a weak accumulation in the interior, suggesting a hollow structure of these foci (Fig. 7B). In addition, we observed that while some of the VP26 structures were still separated from the nuclear membrane by a thin layer of condensed chromatin (Fig. 7B, panels a and b), others displaced the chromatin to such an extent that they virtually gained access to the nuclear membrane, which was visible by virtue of EYFP-gH fluorescence (Fig. 7B, panels c and d). In order to test if these large VP26 foci corresponded to an accumulation of DNA-filled capsids, we codetected VP26 and HSV-1 DNA in wt HSV-1-infected cells (Fig. 7C). While VP26 and HSV-1 DNA colocalized within the RCs, the large VP26 foci did not contain HSV-1 DNA. Assuming that DNA within virions is accessible for FISH, these data suggest that the large VP26 foci do not correspond to accumulations of DNA-filled capsids.

To ascertain that the distribution of the fluorescent virion proteins corresponded to that of the respective wt proteins, we performed infections with wt HSV-1 and detected VP16, gH, and VP26 by immunofluorescence. CLSM analysis of stained cells revealed that the patterns for all three wt virion proteins were very similar to those observed with the recombinant viruses (Fig. 8A to C). However, it has to be noted that the accumulation of VP16 in large foci at the nuclear periphery and their colocalization with VP26 was not observed in wt HSV-1-infected cells stained with VP26- and VP16-specific antibodies (Fig. 8D). This analysis also demonstrated that the structure of the large VP26 foci was identical to that observed with the mRFP-VP26 fusion protein (Fig. 8C, panel h). Interestingly, the proportion of cells displaying such large VP26 foci appeared to be somewhat smaller in wt HSV-1-infected cells than in cells infected with the recombinant viruses.

Time-lapse CLSM of cells infected with either rHSV-RYC or rHSV-RY allowed us to obtain a dynamic view of the interaction between VP16, gH, and VP26 in the infected cells (Fig. 9; see also movies S1 to S3 in the supplemental material). Specifically, the image series demonstrated a very dynamic compartmentalization of VP16-ECFP in the course of infection. While VP16-ECFP initially steadily accumulated in the nuclear RCs and later in the small foci in the periphery of the RCs, there was a very rapid and pronounced recruitment of VP16-ECFP out of the nucleus into the cytoplasm and, in some cells, into the large mRFP-VP26 foci at the periphery of the nucleus in a late stage of infection. This redistribution was fairly rapid and generally occurred within 1 to 2 h (Fig. 9A). In addition, the time-lapse series revealed the progressive accumulation of EYFP-gH at the nuclear membrane and in the perinuclear cytoplasmic pattern (Fig. 9A and B). Finally, the analysis demonstrated that the initially small foci of mRFP-VP26 expanded and coalesced to form much larger foci, which were pushed toward the periphery of the nucleus as infection progressed (Fig. 9A and B).

**Ultrastructural analysis of rHSV-RYC-infected cells.** Electron microscopy revealed clear indications for normal maturation of the triple-fluorescent recombinant HSV-1, rHSV-RYC, with identical phenotypes to wt HSV-1 (Fig. 10). These phenotypes include formation of capsids with occasional crystalline-like accumulation within the nucleus (Fig. 10C), budding of capsids at the inner nuclear membrane (Fig. 10B), budding of capsids at Golgi membranes (Fig. 10D), virions within vacuoles (Fig. 10E), and virions in the extracellular space (Fig. 10F).

**DISCUSSION**

Autofluorescent proteins have been used extensively to study many different biological processes, including the replication cycle of viruses (reviewed in reference 5). Recombinant herpesviruses encoding individual virus proteins fused with autofluorescent proteins have previously been constructed to study several different aspects of the herpesvirus life cycle, including trafficking, assembly, and maturation (11, 13, 15, 17, 20, 35, 39). Here, we report for the first time the construction and time-lapse analysis of a recombinant HSV-1 that simultaneously encodes virus proteins from three different virion compartments, capsid (VP26), tegument (VP16), and envelope (gH), fused with different autofluorescent proteins (mRFP, ECFP, and EYFP, respectively).

Crucial to the construction of the triple-fluorescent recombinant HSV-1 was the availability of a BAC-cloned HSV-1 genome (59), which facilitated the easy manipulation of the virus genome in bacteria. The combination of the HSV-1 BAC with the possibility for both positive and negative selection in bacteria provided by the galK system (62) allowed the serial introduction of the three fusion genes into the virus genome. The reconstitution of recombinant virus progeny and the elimination of the BAC backbone were accomplished following cotransfection of the recombinant HSV-1 BAC DNA with a Cre recombinase-expressing plasmid in mammalian cells (Fig. 1).

Western analysis of infected cells demonstrated that all three fusion proteins were synthesized (Fig. 2). Interestingly, this triple-fluorescent recombinant HSV-1, rHSV-RYC, was replication competent, although with delayed kinetics, and incorporated all three fusion proteins into the different virion compartments. It appeared that the fusion of EYFP to gH was responsible for a delay in the kinetics of virus release (Fig. 3). This is consistent with a previous report describing the fusion of EYFP to the N terminus of gH (39). Although the authors of that study contended that the recombinant virus replicated to titers comparable to those of wt HSV-1, it has to be noted that the wt virus used in their study (strain 17 syn +) reached only a titer of 5.25 × 10⁶ PFU/ml, which is rather low for a wt virus. The fusion of autofluorescent proteins to VP16 and VP26 also seemed to affect virus titers, although there were no indications that fusion to the essential VP16 would have a greater impact on viral replication fitness than fusion to the nonessential VP26. In addition, the analysis did not support the notion that the effects of the individual fusions were additive. Rather it appeared that the addition of at least one autofluorescent fusion protein to a virus protein resulted in a somewhat delayed kinetics of virus production (gH) or reduced...
final titers (VP16 or VP26). Electron microscopy analysis revealed that the triple-fluorescent recombinant HSV-1 was comparable to wt HSV-1 also at the ultrastructural level (Fig. 10). Moreover, CLSM of infected cells demonstrated that the distribution and compartmentalization of the three autofluorescent fusion proteins encoded by rHSV-RYC were comparable to those observed with either wt HSV-1 or recombinants of HSV-1 that encode autofluorescent proteins fused with

FIG. 8. Immunofluorescence staining for VP16, gH, and VP26 in wt HSV-1-infected cells. (A) Immunofluorescence staining for VP16. Vero cells were infected with wt HSV-1 at an MOI of 10 PFU. At the indicated times postinfection, the cells were fixed and stained with the anti-VP16 MAb LP1 and an AF594-conjugated secondary antibody, as well as DAPI. The cells were then observed by CLSM with settings specific for DAPI and AF594. Filled arrowhead, VP16 foci in the periphery of RCs. (B) Immunofluorescence staining for gH. Vero cells were infected and stained as described for panel A, except that the anti-gH MAb LP11 was used. (C) Immunofluorescence staining for VP26. Vero cells were infected and stained as described for panel A, except that the rabbit anti-VP26 PAb VP26/C was used. Panel h shows a magnification of the VP26 focus marked with an arrow. (D) Vero cells were infected as described for panel A, fixed at 16 h p.i., and stained with DAPI, the anti-VP16 MAb LP1 (detected with an AF594-conjugated secondary antibody), and the rabbit anti-VP26 PAb VP26/C (detected with a FITC-conjugated secondary antibody). The cells were then observed by CLSM with settings specific for DAPI, AF594 (VP16, shown in green), and FITC (VP26, shown in red). Images in panels A to D represent single z stacks of the cells.
VP26, gH, or VP16 individually (Fig. 5 to 8) (13, 35, 39). Finally, the strong dot-like association of autofluorescent fusion proteins of three different virion compartments, VP16-ECFP, mRFP-VP26, and EYFP-gH, at plasma membrane protrusions (Fig. 6A and B) supports the hypothesis that these dots indeed are mature virions and that progeny virions incorporate sufficient amounts of the fluorescent fusion proteins to allow their visualization, although this has to be confirmed on the ultrastructural level. Nevertheless, it would be less convincing to draw such a conclusion with a recombinant HSV-1 that encodes only one or two autofluorescent virion proteins.

The major advantage of our approach is the possibility for simultaneously visualizing the distributions and interactions between different virus proteins and virion compartments on the single cell level. Moreover, our strategy allows study of the dynamics of these events in live cells. For example, mRFP-VP26 and VP16-ECFP colocalized within RCs in the nucleus but, in addition, they both also formed foci in the periphery of the RCs that did not colocalize (Fig. 5). In a previous report it was hypothesized that the VP16 foci in the periphery of the RCs may correspond to sites where capsids acquire VP16 (35). Our experiments, however, suggest that this hypothesis is unlikely. In the course of the infection, the mRFP-VP26 foci expanded and coalesced to form larger foci that relocated to the periphery of the nucleus. In the majority of the cells, VP16-ECFP was redistributed from the nucleus to the cytoplasm late in infection, in a process that occurred very rapidly (generally within 1 to 2 h). Of note is that in a subset of cells, VP16-ECFP was, in addition, recruited into the large mRFP-VP26 foci at the periphery of the nucleus (Fig. 5 and 9; see also movies S1 to S3 in the supplemental material). This phenomenon was, however, not observed in wt HSV-1-infected cells stained with VP16- and VP26-specific antibodies, in which VP26, but not VP16, was consistently observed in the large foci at the nuclear periphery (Fig. 8). In contrast, the colocalization of VP26 and VP16 in the cytoplasm late in infection was readily observed in both rHSV-RYC- and wt HSV-1-infected cells (Fig. 5 and 8). There are two possible explanations for this discrepancy: first, the fusion of ECFP to VP16 may have altered some of its biological properties, leading to its recruitment into the large mRFP-VP26 foci at the nuclear periphery. Second, it is conceivable that VP16 and VP26 similarly colocalized in wt HSV-1-infected cells but that the VP16-specific antibody employed did not detect VP16 when present in the

FIG. 9. Time-lapse CLSM of rHSV-RYC- and rHSV-RY-infected cells. Vero cells were infected with rHSV-RYC (A) or rHSV-RY (B) at MOIs of 2 and 0.3, respectively. Cells that just started to accumulate fluorescent proteins were monitored by CLSM with settings specific for ECFP (VP16-ECFP), EYFP (EYFP-gH), and mRFP (mRFP-VP26). Selected frames at the indicated intervals are shown. Images were processed with Imaris software in the surpass view mode. Arrowheads denote the cells described in the text.
large VP26 foci at the periphery of the nucleus, possibly because of an altered conformation of VP16 in these structures. However, the very late appearance of this colocalization (18 to 24 h p.i.) suggests that it likely does not represent a crucial step in the assembly and egress of progeny virus, since infectious progeny are produced already at earlier time points (i.e., 12 h p.i.) (Fig. 3). The accumulation of VP26 in large nuclear foci was previously documented in cells infected with wt HSV-1.
and stained with VP26-specific antibodies, as well as by expression of VP26 fused to GFP. The formation of nuclear VP26 foci was demonstrated to depend on the presence of VP5 and VP22a and to occur in an ATP-dependent manner (8, 11, 13, 32). These VP26 foci were hypothesized to correspond to the sites of capsid assembly, similar to the assemblons described by Ward and coworkers, which contained the capsid proteins ICP35, VP5, and VP19c and formed very late in infection at the periphery of the nuclear RCs (13, 61). Interestingly, Ward et al. (61) detected a partial colocalization between assemblons and VP16 by staining with VP19c- and VP16-specific antibodies. However, this partial colocalization clearly differs from the almost perfect colocalization of VP16-ECFP and mRFP-VP26 in large foci at the nuclear periphery observed in our study (Fig. 5). The ultrastructural correlate of this colocalization remains to be determined. It is possible that the VP26 foci at the nuclear periphery may represent the accumulation of dead-end products, as previously suggested for assemblons (10, 36), to which VP16 is recruited late in infection. This hypothesis is further supported by the finding that these structures do not contain HSV-1 DNA, indicating that they do not correspond to accumulations of DNA-filled capsids (Fig. 7).

In summary, this study demonstrates the feasibility of the construction of a recombinant HSV-1 simultaneously expressing autofluorescent proteins fused to VP16, VP26, and gH. This study sheds light on the spatial and temporal organization of HSV-1 infection at the single-cell level. Specifically, the simultaneous fluorescence labeling of several virion components allowed assessment of the interactions of the different viral proteins in the course of the infection. This approach may be used to address several open questions in HSV-1 biology, for example, the spatial organization of capsid assembly and maturation by fluorescent labeling of several components of the pro-capsid and those of mature capsids. In addition, fluorescently labeled virus proteins may be combined with systems for the live visualization of viral DNA, as previously described for several viruses, such as HSV-1, Epstein-Barr virus, and adenovirus-associated virus (1, 23, 28, 29, 58), to specifically assess the dynamics of the association of viral proteins with viral DNA. Finally, the simultaneous fluorescent labeling of capsid, tegument, and envelope components may prove useful for the study of virus trafficking, for example, to assess and compare the composition of virions transported in an anterograde versus retrograde direction within axons (2–4, 20, 40).
