Received 6 July 2007/Accepted 21 March 2008

Some strains of mouse hepatitis virus (MHV) can induce chronic inflammatory demyelination in mice that mimics certain pathological features of multiple sclerosis. We have examined neural cell tropism of demyelinating and nondemyelinating strains of MHV in order to determine whether central nervous system (CNS) cell tropism plays a role in demyelination. Previous studies demonstrated that recombinant MHV strains, isogenic other than for the spike gene, differ in the extent of neurovirulence and the ability to induce demyelination. Here we demonstrate that these strains also differ in their abilities to infect a particular cell type(s) in the brain. Furthermore, there is a correlation between the differential localization of viral antigen in spinal cord gray matter and that in white matter during acute infection and the ability to induce demyelination later on. Viral antigen from demyelinating strains is detected initially in both gray and white matter, with subsequent localization to white matter of the spinal cord, whereas viral antigen localization of nondemyelinating strains is restricted mainly to gray matter. This observation suggests that the localization of viral antigen to white matter during the acute stage of infection is essential for the induction of chronic demyelination. Overall, these observations suggest that isogenic demyelinating and nondemyelinating strains of MHV, differing in the spike protein expressed, infect neurons and glial cells in different proportions and that differential tropism to a particular CNS cell type may play a significant role in mediating the onset and mechanisms of demyelination.

Multiple sclerosis is a common disabling neurological disease, pathologically characterized by demyelination, loss of oligodendrocytes, and axonal degeneration (25, 26). The mechanisms that culminate in the destruction of oligodendrocytes and loss of central nervous system (CNS) myelin are not well understood. The process is believed to involve a T-cell-mediated autoimmune phenomenon that may be triggered by one or more viral infections (1). Several experimental viral model systems have been instrumental in providing these insights (2). One of the animal models is based on mouse hepatitis virus (MHV)-induced demyelination in mice that mimics the pathology of multiple sclerosis (12, 19, 21, 39, 42). Infection with neurotropic MHV strains produces a biphasic neurological disease, with acute meningoencephalitis preceding the onset of chronic demyelination (21).

Following intracranial inoculation, MHV is first observed in the brain and subsequently spreads into the spinal cord (30). The viral titer reaches its peak at approximately day 5 postinfection. Infectious viral particles are cleared within the first 7 to 10 days after infection, although viral RNA persists in the white matter of the spinal cord for several months (20, 29). Viral RNA persistence has previously been demonstrated in spinal cords of mice infected with demyelinating strains of MHV, including MHV-A59 and JHM (17, 20, 29), and has previously been suggested to be a prerequisite for MHV-induced demyelination. Indeed, MHV-2 and Penn 971 (a nondemyelinating recombinant strain of MHV) (3), which do not persist, also do not cause demyelination (4). Interestingly, the viral RNA of SMHV2-RA59, a chimeric strain (a nondemyelinating strain of MHV, expressing MHV-2 spike gene in the MHV-A59 background, previously called Penn 98-1/2), persists in the spinal cord during chronic infection and, yet, is unable to induce demyelination (4), indicating that viral RNA persistence in the spinal cord per se is insufficient to induce chronic demyelination. If exchanged between strains, genes for the spike protein, which are known to mediate viral entry, may alter the capacity of MHV to infect and replicate in particular CNS cell types (neurons, astrocytes, microglia, and oligodendrocytes) during the acute stage of infection, and therefore influence the induction of chronic demyelination.

Little is known about the involvement of CNS cell tropism in MHV-induced demyelination. It is known, however, that in the CNS, demyelinating MHVs infect a variety of neural cell types, including neurons, astrocytes, oligodendrocytes, microglia, and ependymal cells (15, 19, 21, 43). Recently, by using JHM spike chimeric viruses, Phillips et al. (32) demonstrated that spike gene-mediated neurovirulence of MHV is associated with extensive viral spread in the brain in both neurons and astrocytes.
However, no studies have examined whether nondemyelinating MHV strains infect the same CNS cell types as do demyelinating strains.

We have examined CNS cell tropism of both demyelinating and nondemyelinating MHV strains during the acute stage of infection in order to determine how the infection of a particular cell type(s) influences the likelihood of development of chronic demyelination. This examination entailed asking whether nondemyelinating strains differ in their abilities to infect gray and white matter cells in the spinal cord during acute infection.

We used the recombinant MHVs SJHM-RA59EGFP (highly neurovirulent and demyelinating), RA59EGFP (weakly neurovirulent but demyelinating) (38), and SMHV2-RA59EGFP (neurotropic but nondemyelinating) (33). All three viruses express enhanced green fluorescent protein (EGFP) and are isogenic, except for the spike gene, and differ in their neurovirulence and demyelination properties.

During acute infection, these three isogenic recombinant MHVs differ in spread and also in their CNS cell tropism. Most interestingly, viral antigen of the demyelinating strains is first detected in gray matter, with subsequent localization to white matter; while antigen of nondemyelinating strains is restricted mainly to gray matter, with occasional distribution to white matter. The distribution of viral antigen in white matter during the acute stage of infection may be one of the key factors in chronic viral persistence and induction of demyelination.

**MATERIALS AND METHODS**

**Viruses and cells.** EGFP-expressing recombinant viruses SJHM-RA59EGFP and RA59EGFP are isogenic, except that SJHM-RA59EGFP expresses the JHM spike gene and RA59EGFP carries the A59 spike gene (38). These two EGFP-expressing viruses were generated from our previous studies (38), where they were named SJHM-R1EGFP and S1A59R1EGFP for SJHM-RA59EGFP and RA59EGFP, respectively.

**Construction of SMHV2-RA59EGFP.** To construct the nondemyelinating, EGFP-tagged, isogenic, recombinant strain SMHV2-RA59EGFP, the MHV-2 (a nondemyelinating MHV strain) (3) spike gene was cleaved from pMH54-SMHV2EGFP with AvrII and SbfI restriction digestion and inserted into the pMH54EGFP in place of the A59 spike gene (4). Targeted RNA recombination was carried out as described in our previously published work (38). For each desired recombinant, at least two strains derived from independent recombinations were characterized. EGFP-expressing viruses with the MHV-2 spike gene were labeled SMHV2-RA59EGFP. We previously used this recombinant EGFP-tagged strain of SMHV2-RA59 in our other studies (33).

**Inoculation of mice.** Four-week-old, MHV-free C57BL/6 (B6) male mice (National Cancer Institute, Frederick, MD) were used in all experiments. Mice were anesthetized with isoflurane (IsoFlo; Abbott Laboratories, North Chicago, IL) prior to inoculation. For intracranial inoculations, 20 μl of diluted virus (in phosphate-buffered saline [PBS] containing 0.167% gelatin) was injected into the left cerebral hemisphere. Mock-infected controls were inoculated with 0.167% gelatin (gel saline). All organs were weighed and stored frozen at −80°C. Brains and livers were homogenized, and viral titers were determined by plaque assay on L2 cell monolayers (4).

Histopathological analysis. For analysis of organ pathology, mice were infected intracranially, sacrificed at various times (days 3, 5, 7, and 10 postinfection), and perfused with 5 ml of saline, followed by 10% phosphate-buffered formalin. Brains and spinal cords were removed, and tissues were embedded in paraffin and sectioned for staining. Brain and spinal cord sections were stained with hematoxylin and eosin (H&E) and used for pathological evaluations by light microscopy. For an assessment of demyelination, mice were inoculated intracranially with 0.5 LD50 (0.5LD50) dose (eight mice per virus strain) and sacrificed at day 30 postinfection. Spinal cord sections were stained with Luxol fast blue to detect plaques of demyelination. We repeated the demyelination experiment five times, with eight mice in each group.

Demyelination was quantified by examining four quadrants from two different levels of spinal cord sections for each mouse; thus, approximately 80 quadrants were examined for each virus. All slides were coded and read in a blinded fashion (4).

**Immunohistochemical analysis.** Immunohistochemical analysis was performed by the avidin-biotin-immunoperoxidase technique (Vector Laboratories, Burlington, CA) using 3,3′-diaminobenzidine as the substrate and a 1:20 dilution of monoclonal antibody directed against the nucleocapsid protein (N) of MHV-JHM (monoclonal antibody clone 1-16-1 [kindly provided by Julian Leibowitz]). Control slides from mock-infected mice were incubated in parallel. All slides were read in a blinded manner.

**Immunofluorescence.** Mice were inoculated intracranially and sacrificed (five mice per group) at days 3, 5, and 7 postinfection. Infected mice were perfused transcardially with PBS, followed by cold PBS containing 4% paraformaldehyde and finally with 10 ml of PBS containing 10% sucrose. Brains were removed and placed at 4°C for 4 h in 10% sucrose, followed by 30% sucrose overnight. Tissues were embedded in OCT medium (Tissue Tek, Hatfield, PA), sectioned sagittally with a microtome to 6-μm thickness, and mounted on glass slides. Some sections were stained with H&E, while others were left unstained for EGFP detection and immunofluorescence. To detect EGFP fluorescence without immunostaining, frozen brain sections were fixed in ice-cold 95% ethanol for 20 min, incubated at room temperature in ice-cold PBS for 10 min, and then mounted in 4,6-diamidino-2-phenylindole (Invitrogen, Carlsbad, CA) using Gel/Mount (Burlington, CA) using 3,3′-diaminobenzidine as the substrate and a 1:20 dilution of monoclonal antibody directed against the nucleocapsid protein (N) of MHV-JHM (monoclonal antibody clone 1-16-1 [kindly provided by Julian Leibowitz]). Control slides from mock-infected mice were incubated in parallel. All slides were read in a blinded manner.

**Double-label immunofluorescence.** Frozen tissue sections were washed with PBS at room temperature in a humidified chamber, incubated for 10 min at room temperature with 1 mg/ml NaBH4 in PBS to reduce autofluorescence, washed, incubated for 1 h at room temperature with 1 ml of PBS containing 1% Triton X-100 (TX), and incubated with a 1:500 dilution of mouse monoclonal antibody to goat IgG (Jackson Laboratory, Maine). Control slides were incubated with preimmune rabbit sera and sections from mock-infected mice were incubated with secondary antibodies only. Tissue sections were sequentially washed with PBS plus TX and with PBS and mounted and visualized by fluorescence microscopy with a 40× UPlanApo oil immersion objective, with the iris diaphragm partially closed to limit the contribution of out-of-plane fluorescence, and with filter packs suitable for green fluorescence (U-MWIBA; exciter, BP460-490; beam splitter, DM505; emitter, BAS155-550) and red fluorescence (U-MNG; exciter, BP530-550; beam splitter, DM570; emitter, BA590-800×). Images were acquired with a Hamamatsu Orca-1 charge-coupled device camera and Image-Pro image analysis software (Media Cybernetics, Silver Spring, MD).
RESULTS

Comparative pathogenesis of demyelinating and non-demyelinating strains. We have compared the pathogenesis of SJHM-RA59EGFP, RA59EGFP, and SMHV2-RA59EGFP, which are isogenic, except for the spike gene (Fig. 1). We used a 0.5LD<sub>50</sub> dose for these pathogenesis studies; for SJHM-RA59EGFP, this dose was 5,000 PFU; for RA59EGFP, it was 20,000; and for SMHV2-RA59EGFP, it was 100 PFU. We infected eight mice in each group and repeated the experiment five times altogether. Out of a total of 40 mice infected for each group, 26 mice survived in the SJHM-RA59EGFP-infected group, 30 mice survived in the RA59EGFP-infected group, and 24 mice survived in the SMHV2-RA59EGFP-infected group by day 30 postinfection. Brain and spinal cord sections from mice infected intracranially with SJHM-RA59EGFP, RA59EGFP, and SMHV2-RA59EGFP were stained either with H&E or Luxol fast blue and analyzed by light microscopy. No demyelination was observed in any of the mice infected with SMHV2-RA59EGFP. Associated lymphocytic inflammation was more severe in SJHM-RA59EGFP-infected mice than in brains infected by RA59EGFP and SMHV2-RA59EGFP, and brain sections from RA59EGFP showed comparatively more parenchymal inflammation than did those from SMHV2-RA59EGFP. Associated lymphocytic meningitis was also present in all three strains (Fig. 2, lower panel). Pathogenic properties of these viruses are summarized in Table 1.

Liver pathology consisted of moderate to severe hepatitis following RA59EGFP and SMHV2-RA59EGFP infection, a result similar to those for the respective parental recombinant strains (28). The infection is characterized by multiple foci of necrosis throughout the liver (data not shown). We did not observe any liver pathology in SJHM-RA59EGFP-virus-infected mice.

Individual strains exhibit different cellular tropism. To compare the cellular tropism of demyelinating and non-demyelinating MHV strains, we performed double-label immunofluorescence on sagittal brain sections. Mice were inoculated intracranially with a 0.5LD<sub>50</sub> dose of SJHM-RA59EGFP, RA59EGFP, and SMHV2-RA59EGFP. Infected animals were sacrificed at days 3 and 5 postinfection, and frozen sections were made. EGFP fluorescence was used to detect viral antigen-positive cells, and immunofluorescence was carried out using MAP2b as a neuron-specific marker and GFAP as an astrocyte-specific marker. Sections were systematically scanned in a blinded fashion. Representative pictures of dual-color fluorescence of viral antigen plus MAP2b and viral antigen plus GFAP are shown in Fig. 3 and 4, respectively. Visual microscopic observations show that SJHM-RA59EGFP infects neurons more than the other two strains. On the contrary, in SJHM-RA59EGFP-infected mice, only a very small number of viral antigen-positive cells were positive for the astrocyte-specific marker GFAP, whereas in RA59EGFP-infected mice, EGFP-positive cells partially overlapped with GFAP staining. It appears that there are CNS cells other than astrocytes that are infected by RA59EGFP. More surprisingly, in SMHV2-RA59EGFP-infected mice, EGFP-positive cells were in complete overlap with GFAP, demonstrating that most infected cells were astrocytes. Thus, SJHM-RA59EGFP is predominantly neuron tropic, but may be less able to infect astrocytes. RA59EGFP is multitropic and infects neurons as well as astrocytes and also other cell types in the CNS; SMHV2-RA59EGFP infects mainly astrocytes and neurons with markedly reduced efficiency. Simultaneously, to avoid a high percentage of mortality at high virus dose and produce an optimal level of viral replication that does not damage the tissue to a degree that makes microscopic observation unsuitable, we chose a 0.5LD<sub>50</sub> dose. However, to ensure that tropism of virus during the acute stage of infection does not depend on the dose, we also performed ex-
experiments which demonstrate that the cellular tropism of SMHV2-RA59EGFP at 500 PFU and 1,000 PFU at day 5 was similar to that at 100 PFU. We also carried out infections with 500 PFU and 1,000 PFU of SJHM-RA59EGFP and RA59EGFP and observed the same CNS cell tropism as at a higher dose, only with fewer infected cells.

Demyelinating and nondemyelinating strains differ in their viral antigen localization in gray and white matter of the spinal cord. To examine whether demyelinating and nondemyelinating strains differ in viral antigen distribution in spinal cord gray and white matter, we collected spinal cord tissues from SJHM-RA59EGFP-, RA59EGFP-, and SMHV2-RA59EGFP- infected mice at days 5 and 7 postinfection. Cross sections from several regions of all spinal cords were stained with viral antinucleocapsid antiserum. Ten mice were sacrificed per time point following infection by a particular viral strain. At day 5 postinfection, viral antigens were observed mainly in the gray matter of the spinal cord for all three strains, but in SJHM-RA59EGFP- and RA59EGFP-infected mice some viral antigen was also detected in the white matter (Fig. 5, upper panel). At day 7, most of the viral antigen in SJHM-RA59EGFP and RA59EGFP was found in white matter, whereas SMHV2-RA59EGFP viral antigen remained restricted mainly to gray matter, with occasional distribution to white matter (Fig. 5, middle panel). In SMHV2-RA59EGFP-infected mice, viral antigen was observed occasionally in the white matter (3 of 60 spinal cord sections), and in some spinal cord sections of SMHV2-RA59EGFP, viral antigen was detected at the gray-

FIG. 2. CNS pathology of EGFP-expressing MHVs. The upper panel shows the observed demyelination. Luxol fast blue stained spinal cord sections of mice infected with SJHM-RA59EGFP, RA59EGFP, or SMHV2-RA59EGFP, at day 30 postinfection. Thin arrows indicate a region of demyelination, and arrowheads indicate normal myelinated area of white matter. Original magnification, ×20. The middle panel shows the observed encephalitis. The microglial nodules shown are from H&E-stained basal forebrain sections of mice infected with EGFP-tagged MHVs at day 7 postinfection. Arrows indicate the microglial nodules (microglia with elongated nuclei) and lymphocytes in the vicinity of neurons in mice infected with SJHM-RA59EGFP, RA59EGFP, and SMHV2-RA59EGFP. Original magnification, ×200. The lower panel shows the observed meningitis. H&E-stained sections from the basal forebrain of mice infected with EGFP-tagged MHVs at day 7 postinfection; shown are SJHM-RA59EGFP, RA59EGFP, and SMHV2-RA59EGFP. In all cases, there is a brisk leptomeningeal lymphocytic inflammatory infiltrate. Original magnification, ×200.
white matter junction, as shown in Fig. 5, lower panel. We repeated the experiment three times, with 10 mice in each group, and we observed similar viral antigen distributions in all three experiments.

**DISCUSSION**

The current studies highlight the important role of neural cell tropism of viral antigen in MHV-induced demyelination in the CNS. Localization studies showed that MHV strains that differ in their neurovirulence and abilities to demyelinate also differ in their abilities to infect particular CNS cell types. SJHM-RA59EGFP infects neurons with greater efficiency, and infection may spread more rapidly than RA59EGFP, while SMHV2-RA59EGFP infects neurons with limited efficiency. This is consistent with previous findings (32) that the degree of neurovirulence is dependent not only on neuronal tropism but also on the number of infected neurons and the spread of the infection through neurites. Evidence from closely related strains of neurotropic viruses, including human immunodeficiency virus, Thielar’s murine encephalitis virus, and reovirus, supports the hypothesis that CNS cell tropism and spread in CNS cells play a major role in the distribution and type of CNS lesions (18, 41, 45). Studies with lymphocytic choriomeningitis virus and human immunodeficiency virus also suggest that virus strains that exhibit rapid spreading are associated with increased immune-mediated pathology (27, 44). It has previously been demonstrated that MHV spread to the spinal cord white matter occurs very rapidly, and protection from demyelination can be achieved by inhibiting this viral spread during the acute phase of infection by recruiting high numbers of MHV-specific CD8+ T cells (23).

Our study highlights the diverse modes of infection that may lead to demyelination. In our study, the nondemyelinating strain is less able to infect and spread through neurons; on the
other hand, demyelinating strains are highly neuron tropic and spread rapidly through neurites. In contrast, it has previously been observed that a temperature-sensitive demyelinating mutant of JHM infects mainly nonneuronal cells (having a strong tropism specifically for astrocytes) and causes white matter lesions (11, 16). Similarly, it has previously been demonstrated that a monoclonal-antibody-selected JHM variant, a spike protein mutant, infects the glial cells predominantly in the CNS, causing subacute demyelination (8, 9). Interestingly, the neutrotropic and nondemyelinating MHV3 strain, which has an in vitro tropism for neurons, ependymal cells, and meningeal cells, but not for astrocytes and oligodendrocytes, can induce an initial ependymitis, meningitis, and encephalitis in the absence of white matter lesions (40). Our in vivo data demonstrate that the highly neurovirulent strain SJHM-RA59EGFP has very little tropism for astrocytes. RA59EGFP and SMHV2-RA59EGFP infect astrocytes with similar efficiencies. As demyelinating and nondemyelinating strains produce similar infections in astrocytes, it appears that astrocytic infection during the acute stage alone may not determine the onset of demyelination. Our observations suggest that astrocyte tropism may be a relevant factor in persistent infection, but direct astrocytic infection alone may not be sufficient to induce demyelination.

The development of chronic demyelination involves the replication and spread of viral antigen in the spinal cord during the acute stage of infection and the persistence of viral RNA in white matter. This is substantiated by our observations on viral spread of nondemyelinating MHV in the spinal cord, where viral antigen during the acute phase of infection is restricted mainly to gray matter. In contrast, viral antigen from demyelinating strains spreads from gray to white matter during the acute stage of infection. Specifically, after intracranial infection and replication, viral antigens from the demyelinating strains SJHM-RA59EGFP and RA59EGFP are seen mostly in spinal cord gray matter at day 5 postinfection and then in white matter at day 7 postinfection. Our results establish that demyelinating and nondemyelinating strains differ in their viral antigen distribution in gray matter and white matter during acute infection. Viral persistence observed previously in SMHV2-RA59-infected mouse spinal cords during the chronic phase of infection may be due to the presence of viral RNA in gray matter (4). Viral RNA for demyelinating strains is known to persist mainly in the white matter (29). Due to lack of viral RNA persistence in the white matter, which is essential for the induction of demyelination during chronic infection, SMHV2-RA59 is unable to induce demyelination. It is possible that cell-specific viral RNA persistence is necessary for demyelination. These combined observations reinforce the importance of glial cell infection in the onset of demyelination.

It can also be argued that the spread of viral antigen from neuron to neuron and from neuron to glial cells plays a critical role in the induction of chronic-stage demyelination. Although there are no experimental data to demonstrate this argument, it can be suggested, based on our current neural cell tropism...
studies, that neuroinvasion by MHV may require entry into the nerve endings, transport to the cell body, replication in the cell body, axonal transport to the synapse, and transneuronal viral spread. Similar mechanisms of axonal transport of virus particles have been observed for the alphaherpesviruses, herpes simplex virus, and pseudorabies virus (6, 7). Furthermore, Theiler’s murine encephalitis virus, a nonenveloped virus that like MHV, causes chronic demyelination in mice, is able to traffic from the axon into the surrounding myelin in the absence of cell lysis (37). Thus, by a mechanism involving transneuronal spread, MHV may gain access to synaptically linked neuronal circuits and glial cells. It is not clear, however, which type(s) of glial cells must be infected in order to promote the development of MHV-induced chronic demyelinating disease. Our studies focused mainly on neurons and astrocytes, as they represent the majority of infected cells during the acute stage of MHV infection, but we cannot disregard oligodendrocytes. It has previously been demonstrated that MHV can infect oligodendrocytes (22), but the direct cytolytic effect of MHV on oligodendrocytes is unclear (13, 14). Direct viral infection of oligodendrocytes may contribute to MHV-induced demyelination, as observed in another human demyelinating disease, progressive multifocal leukoencephalopathy, which is caused by JC virus infection of oligodendrocytes (24, 35). Experiments are under way to optimize techniques that will facilitate detection of oligodendrocytes in MHV-infected tissues.

In summary, combined assessment of brain and spinal cord infections allows us to infer an indirect role of neuronal cell tropism in demyelination. SJHM-RA59EGFP and RA59EGFP infection can both spread from gray matter to white matter and

FIG. 5. Viral antigen expression in spinal cord sections of mice infected with EGFP-expressing viruses. Mice were inoculated intracranially with SJHM-RA59EGFP, RA59EGFP, and SMHV2-RA59EGFP. Mice were sacrificed at days 5 and 7 postinfection, and spinal cord sections were stained with anti-nucleocapsid antiserum. Representative hemisections and complete sections of spinal cords are shown from the cervical regions of the spinal cords of mice infected on day 5 (upper panel) and day 7 (middle panel). In SMHV2-RA59EGFP-infected mice, occasional viral antigen distribution in the white matter and gray-white matter junction is shown in the lower panel.
induce demyelination. The inability of the nondemyelinating strain of MHV, SMHV2-RA59, to spread from gray matter to white matter cells in the spinal cord may be due to its inefficient spread through neurites. Acute-stage inflammation and chronic-stage demyelination may be two independent phenomena; however, acute-stage neuronal infection and the lack of viral spread from neuronal to glial cells are likely key elements in the induction of demyelination.
