Role of Interleukin-2 and Herpes Simplex Virus 1 in Central Nervous System Demyelination in Mice

Kevin R. Mott, Mandana Zandian, Sariah J. Allen, Homayon Ghiasi
Center for Neurobiology and Vaccine Development, Ophthalmology Research, Department of Surgery, Cedars-Sinai Medical Center, Los Angeles, California, USA

We have reported previously that ocular infection of different strains of mice with recombinant herpes simplex virus 1 (HSV-1) constitutively expressing interleukin-2 (IL-2) provokes central nervous system (CNS) demyelination and optic neuropathy, as determined by changes in visual evoked cortical potentials and pathological changes in the optic nerve and CNS, whereas recombinant viruses expressing IL-4, gamma interferon, IL-12p35, IL-12p40, or IL-12p70 do not induce this neuropathy. The goal of this study was to dissect the mechanism underlying the interplay between the immune system (elevation of IL-2) and an environmental factor (infection with HSV-1) that elicits this pathology. Similar results were obtained upon delivery of IL-2 into the mouse brain using osmotic minipumps or injection of mice with recombinant IL-2 protein, IL-2 DNA, or IL-2 synthetic peptides prior to infection with wild-type (wt) HSV-1 strains McKrae and KOS. The critical role of IL-2 is further supported by our data, indicating that a single mutation at position T27A in IL-2 completely blocks the HSV-1-induced pathology. This study shows a novel model of autoimmunity in which viral infection and enhanced IL-2 cause CNS demyelination.

Several lines of evidence implicate interleukin-2 (IL-2) in the pathology of multiple sclerosis (MS) (1–4). Patients with MS have elevated levels of IL-2 in their sera and cerebrospinal fluid (CSF) (1–4). The soluble IL-2 receptor (sIL-2R) is also elevated in the sera and CSF of patients with MS (3, 5–10). These clinical findings of elevated IL-2 levels (and lower than normal IL-4 levels) in the sera of MS patients suggest a possible link between IL-2 and the onset of MS. Furthermore, supernatants harvested from T lymphocytes of MS patients cause damage to myelin and glial cells in vitro (11, 12), suggesting that the MS T lymphocytes produce demyelination factors and are activated in vivo.

In order to investigate the role of cytokines in demyelination in a viral model of MS, we have constructed a panel of recombinant herpes simplex virus 1 (HSV-1) isolates that constitutively express murine cytokines, including IL-2 (13), IL-4, gamma interferon (IFN-γ), IL-12p35, or IL-12p40 (14–16). Using these viruses, we have shown that infection of different strains of mice with a recombinant HSV-1 strain constitutively expressing IL-2 (HSV–IL-2), but not HSV–IL-4, HSV–IFN-γ, HSV–IL-12p35, or HSV–IL-12p40, results in demyelination of the optic nerves (ONs), the spinal cords (SCs), and the brains of the infected mice, as determined by histologic examination of tissues obtained at necropsy (17, 18). In addition, the HSV–IL-2–infected mice developed optic neuropathy, as determined by changes in the visual evoked cortical potentials (VECPs) (18). Using knockout mice, deletion, and transfer studies, we found that both CD8+ and CD4+ T cells contributed to HSV–IL-2–induced central nervous system (CNS) demyelination, with CD8+ T cells being the primary inducers (19). We have also found that infection of mice with a recombinant HSV-1 isolate expressing IL-12p70 or injection of mice with IL-12p70 DNA blocks the CNS demyelination induced by HSV–IL-2 (19, 20).

Since the recombinant HSV–IL-2 is not a naturally occurring virus, we used an Alzet osmotic minipump to transfer IL-2 into the brains of recipient mice prior to ocular infection with wild-type (wt) HSV-1 (rather than HSV–IL-2). We also tested the effect of administration of IL-2 DNA, IL-2 site-specific mutants, and synthetic peptide fragments prior to infection with wt HSV-1. We demonstrate that a single mutation in amino acid (aa) 27 of IL-2 abolishes CNS demyelination in mice ocularly infected with wt HSV-1. Thus, analysis of the mechanisms by which the enhanced levels of IL-2 in combination with viral infection elicit CNS demyelination suggests that full-length IL-2 is not required to induce CNS demyelination and further suggests that the region of IL-2 that is involved in CNS demyelination involves the region of IL-2 at aa 27. Collectively, these results provide evidence that this HSV-1 model represents a valid alternative to other commonly used models of MS.

MATERIALS AND METHODS

Ethics statement. All animal procedures were performed in strict accordance with the Association for Research in Vision and Ophthalmology Statement for the Use of Animals in Ophthalmic and Visual Research (http://www.arvo.org/About_ARVO/Policies/Statement_for_the_Use_of_Animals_in_Ophthalmic_and_Visual_Research/) and the guidelines in the National Research Council’s Guide for the Care and Use of Laboratory Animals (21). The animal research protocol was approved by the Institutional Animal Care and Use Committee of Cedars-Sinai Medical Center (protocol 2841).

Mice and viruses. Female BALB/c and C57BL/6 mice (age, 6 weeks) were purchased from The Jackson Laboratory. Plaque-purified HSV-1 strain McKrae (virulent wild type) or KOS (avirulent wild type) and a recombinant HSV-1 strain expressing IL-2 (13) were grown in rabbit skin (RS) cell monolayers in minimal essential medium (MEM) containing 5% fetal calf serum (FCS), as described previously (13, 14, 16). The McKrae virus strain is virulent at an infectious dose of 2 × 105 PFU/eye, whereas the KOS virus strain and HSV–IL-2 are attenuated. We have shown previously that the recombinant HSV–IL-2 expresses IL-2 at high levels in different tissues (13).

Microfluidic pumps delivering rIL-2 were implanted subcutaneously into the side of mice. Female C57BL/6 mice were treated by continuous infusion of purified mIL-2 at 10 µg/24 h over successive 14-day periods. The pumps were inserted i.c. into the back of the skull of the mice through a small skin incision, and IL-2 was delivered into the cerebral ventricles using the Alzet brain infusion kit 1. Wound edges were repaired with surgical clips. Most animals began to regain weight 3 to 4 days after surgery. Osmotic pumps were loaded under sterile conditions with 30 µg of mIL-2 (Peprotech) in 100 µl of PBS. Two weeks after IL-2 infusion, some mice were ocularly infected with 2 × 10^5 PFU/eye of HSV-1 strain McKrae. Control mice were mock infected with a similar volume of medium without HSV-1 infection. Histologic analyses of IL-2 infusion in HSV-1-infected mouse CNS. (A) Results obtained when the pump was inserted i.c.; (B) results obtained when the pump was inserted in the side.

**Murine recombinant IL-2 (rIL-2) infusion.** An Alzet miniosmotic pump (Alzet brain infusion kit 1; Cupertino, CA) was intracranially (i.c.) implanted into the back of the skull of female C57BL/6 mice through a small skin incision. Wound edges were repaired with surgical clips. Most animals began to regain weight 3 to 4 days after surgery. The osmotic pumps were loaded under sterile conditions with 30 µg of purified murine IL-2 (mIL-2; Peprotech, Rocky Hill, NJ) in 100 µl of phosphate-buffered saline (PBS), and 1 µg IL-2 was continuously infused for 24 h. Two weeks after IL-2 infusion, some mice were ocularly infected with 2 × 10^5 PFU/eye of HSV-1 strain McKrae or KOS. Control mice were mock infected with a similar volume of medium without HSV-1 infection. Histologic analyses of IL-2 infusion in HSV-1-infected mouse CNS. (A) Results obtained when the pump was inserted i.c.; (B) results obtained when the pump was inserted in the side.

**DNA injection.** The complete open reading frame (ORF) of murine IL-2 or the IL-2A, IL-2B, IL-2A1, or IL-2A2 fragment, as well as that of full-length IL-2 with one mutation or three mutations, was cloned into the BamHI site of the vector. Microfluidic pumps were loaded under sterile conditions with 30 animals. The osmotic pumps were implanted into the back of the skull of female C57BL/6 mice through a small skin incision, and IL-2 was delivered into the cerebral ventricles using the Alzet brain infusion kit 1. Wound edges were repaired with surgical clips. Most animals began to regain weight 3 to 4 days after surgery. The osmotic pumps were loaded under sterile conditions with 30 µg of mIL-2 (Peprotech) in 100 µl of PBS. Two weeks after IL-2 infusion, some mice were ocularly infected with 2 × 10^5 PFU/eye of HSV-1 strain McKrae. Control mice were mock infected with a similar volume of medium without HSV-1 infection. Histologic analyses of IL-2 infusion in HSV-1-infected mouse CNS. (A) Results obtained when the pump was inserted i.c.; (B) results obtained when the pump was inserted in the side.

**Peptide synthesis.** A panel of 32 overlapping murine IL-2 peptides spanning the entire IL-2 protein sequence (15-mers with 10-aa overlaps) was synthesized by Mimotopes (San Diego, CA), and the peptide sequences are as follows: peptide 1, MYSMQASCVTLTV; peptide 2, LA SCVTLTTLVLLVNS; peptide 3, TLTLLVLLVNSAPTSS; peptide 4, LLVNSA PTSSSTSSS; peptide 5, APTSSSTSSSTASEAQ; peptide 6, SSSTTAAEQQQQQ; peptide 7, TAEAAQQQQQQQQQQQ; peptide 8, QQQQQQQQQQQQQ; peptide 9, QQQQQQQQQQQ; peptide 10, QHLEQL LMDLQELLS; peptide 11, LLLMDLQELLSREMENY; peptide 12, QELLSR MENYRNKL; peptide 13, RMENYRNKLPRMLT; peptide 14, RNKL PRMLTFKFLY; peptide 15, PRMLTFKFLPKQAT; peptide 16, FKFLPK QAITEKLDL; peptide 17, PKQATEKLDLQCTLED; peptide 18, ELKDLQ CLEDELGPI; peptide 19, QCLEDELGPIRLVLDLQSK; peptide 21, RHVLIDILTQSKQFLE; peptide 22, LTQSKSFQ LEDAENF; peptide 23, SFQLEDAENFISNIR; peptide 24, DAENFISNIR VTVKE; peptide 25, ISNIRTVVVLKGD; peptide 26, VTVKVLKGD NTFC; peptide 27, LKGDNTFCQFDDE; peptide 28, NTFCQFDDE SATVV; peptide 29, QFDDESATVVDLFR; peptide 30, SATVVFDLRR WIAFC; peptide 31, DFLRWWIAFCQSI; and peptide 32, WLAFCQSI TSPQ. The purity of the original peptides synthesized was at least 90%. All peptides were dissolved in dimethyl sulfoxide at a concentration of 1 µg/µl and stored at −20°C.

**IL-2 peptide injection.** Mice were injected 3 times with 1 µg of each peptide individually or with combined peptides in adjuvant. On day 0, five mice per group were injected subcutaneously in the shoulder with each individual peptide or combinations of peptides in CFA; on days 7 and 14, the mice were injected with each individual peptide or combinations of peptides in IFA. As negative controls, mice were similarly injected with adjuvant alone. Injected mice were ocularly infected 4 h after the third injection.

**Ocular infection.** Mice were ocularly infected with 2 × 10^5 PFU of strain McKrae, strain KOS, or recombinant HSV–IL-2 per eye. Each virus was suspended in 2 µl and stored at −80°C.

Microosmotic pumps delivering rIL-2 were implanted subcutaneously into the side of C57BL/6 mice, and 14 days later the mice were ocularly infected with HSV-1 strain McKrae. Demyelination was assessed at 14 days p.i. The complete open reading frame (ORF) of murine IL-2 or the IL-2A, IL-2B, IL-2A1, or IL-2A2 fragment, as well as that of full-length IL-2 with one mutation or three mutations, was cloned into the BamHI site of the vector. Microfluidic pumps were loaded under sterile conditions with 30 animals. The osmotic pumps were implanted into the back of the skull of female C57BL/6 mice through a small skin incision, and IL-2 was delivered into the cerebral ventricles using the Alzet brain infusion kit 1. Wound edges were repaired with surgical clips. Most animals began to regain weight 3 to 4 days after surgery. The osmotic pumps were loaded under sterile conditions with 30 µg of mIL-2 (Peprotech) in 100 µl of PBS. Two weeks after IL-2 infusion, some mice were ocularly infected with 2 × 10^5 PFU/eye of HSV-1 strain McKrae or KOS. Control mice were mock infected with a similar volume of medium without HSV-1 infection. Histologic analyses of IL-2 infusion in HSV-1-infected mouse CNS. ground were infected with the KOS virus rather than the McKrae virus. Corneal scarification was not used in this study for either strain.

Preparation of ON, SC, and brain for pathological analysis. The ONs, SCs, and brains of infected mice were removed at necropsy on day 14 p.i. The ONs, SCs, and brains were collected from experimental and control mice and then placed in Tissue-Tek OCT embedding medium (Sakura Finetek, Torrance, CA) and stored at −80°C. Transverse sections of each tissue (thickness, 8 to 10 μm) were cut, air dried overnight, and fixed in acetone for 3 min at 25°C (23). Demyelination in each section was confirmed by monitoring adjacent sections.

Analysis of demyelination using LFB staining. The presence or absence of demyelination in the ONs, SCs, and brains of infected mice was evaluated using LFB staining of formalin-fixed sections of ON, SC, and brain as we described previously (17). Every 4th section of ON, SC, and brain was stained with LFB.

Statistical analysis. Fisher’s exact tests were performed using the computer program Instat (GraphPad, San Diego, CA) to compare demyelination in infected mice with the absence of demyelination in control groups. Results were considered statistically significant when the P value was <0.05.

RESULTS

Murine IL-2 infusion following ocular HSV-1 infection induces demyelination in mice infected with wt HSV-1. Our published data establish that ocular infection of mice with HSV–IL-2 elicits demyelination of the optic nerve, spinal cord, and brain (18–20, 24). In these studies, we looked at the time course of appearance of demyelination in mice infected with HSV–IL-2 (18–20, 24). Demyelination was not detected in any of the HSV–IL-2-infected mice on day 3 or 7 p.i.; however, demyelination was initially detected on day 10 p.i. Demyelination was also detected on days 30 and 60 p.i. Overall, the patterns of demyelination plaques observed on days 10, 30, 60, and 75 p.i. were similar to those observed on day 14. Thus, in this study, we looked at demyelination on day 14 p.i. As the recombinant HSV–IL-2 is not a naturally occurring virus, we generated an alternative approach for delivery of the IL-2 using an Alzet microosmotic pump loaded with murine IL-2 protein, as described in Materials and Methods. Mice were ocularly infected with virulent HSV-1 strain McKrae or mock infected and sacrificed at 14 days p.i. Representative photomicrographs of Luxol blue-stained sections of the brain, SC, and ON from mice infected with McKrae and mIL-2, mice not infected but treated with mIL-2, or mice infected and not treated with mIL-2 are shown in Fig. 1. Consistent with the results obtained when mice were infected with HSV–IL-2 (18–20, 24), administration of murine IL-2 using an implanted miniature osmotic pump and ocular infection with wt HSV-1 induced demyelination in the ON, SC, and brain of all mice tested (Fig. 1A, rIL-2 protein + HSV-1) but was not observed in mice treated with murine IL-2 in the absence of ocular infection (Fig. 1A, rIL-2 protein) or in mice infected with HSV-1 alone (Fig. 1A, HSV-1). Similar results were obtained when this series of experiments was repeated using the avirulent HSV-1 strain KOS (data not shown).

In contrast, when microosmotic pumps were implanted subcutaneously in the side of the mice, 2/7 (28%) mice showed demyelination in their brain, 4/7 (57%) mice showed demyelination in their spinal cord, and none of the mice showed demyelination in their optic nerves following infection with wt HSV-1 strain McKrae (Fig. 1B and Table 1). Previously, it was shown that rIL-2/IL-2 monoclonal antibody (MAb) complexes increase the bio-
Injection of mice with IL-2 DNA induces CNS demyelination following ocular HSV-1 infection. It has been shown previously that DNA vaccine-encoded immunogens can elicit an immune response (26, 27). To test our hypothesis, we injected IL-2 DNA i.m. into female BALB/c mice to determine if this might induce demyelination following ocular infection with wt HSV-1. Injections were done at 21, 14, and 7 days before ocular infection with avirulent HSV-1 strain KOS. As a negative control, some mice were similarly injected with IL-4 DNA or vector DNA. Demyelination in the CNS of infected mice was measured on day 14 p.i. Demyelination was observed in the CNS of BALB/c mice injected with either the IL-2A1 or IL-2A2 DNA fragment and ocularly infected with wt HSV-1 strain McKrae, demyelination was detected in the mice injected with the IL-2A1 fragment but not those injected with the IL-2A2 fragment (Fig. 3). Thus, our results suggest that the region of IL-2 that is involved in CNS demyelination resides within aa 1 to 42 of IL-2 and that full-length IL-2 is not required to induce CNS demyelination. Similar to our results with the IL-2A fragment, it was previously shown that this region of IL-2 is essential for its biological activity (28).

Fine mapping of the region of IL-2 that causes CNS pathology using IL-2 synthetic peptides. The results presented above suggest that the IL-2 protein and IL-2 DNA can cause CNS pathology in ocularly infected mice. Our DNA mapping results also suggested that full-length IL-2 is not required for CNS pathology. To further finely map whether a specific region of IL-2 is required for CNS pathology, we synthesized 32 peptides that cover the entire IL-2 sequence and overlapped by 10 aa. Mice were given 2 subcutaneous injections of each peptide or a mixture of peptides that was either coupled to keyhole limpet hemocyanin (KLH; Pierce Chemical) or left uncoupled. Full-length rIL-2 protein was logical activity of preexisting rIL-2 (25). As the half-life of rIL-2 in the circulation is short, we compared the delivery of rIL-2 protein alone to the delivery of rIL-2 protein plus anti-IL-2 MAb (clone S4B6-1), which has been reported to increase the IL-2 half-life (25). However, we observed no differences in the severity or duration of demyelination between the two groups (not shown). As we did not observe any differences between mice injected with rIL-2 protein alone and mice injected with rIL-2 protein and anti-IL-2 MAb, all of the subsequent experiments described in this study used only rIL-2 protein without incubating it with anti-IL-2 MAb.

a C57BL/6 mice were injected with 10 μg of each peptide at 7 days and 4 h before ocular infection with HSV-1 strain McKrae. The first injection included CFA, and the second injection included IFA. Demyelination was assessed at 14 days p.i. b Boldface amino acids indicate areas of overlap between the peptides.
used as a positive control. The first injection was in CFA, while the second injection was in IFA. Demyelination was determined at 14 days p.i. with HSV-1 strain McKrae. As summarized in Table 2 (corresponding photomicrographs are presented in Fig. 4), infected mice that received peptides which contained the STSSS sequence (aa 26 to 30) developed demyelination of the optic nerve, spinal cord, and brain, while other regions of IL-2 did not induce demyelination. We did not detect any differences in the level of demyelination between mice injected with peptides coupled to KLH and mice injected with peptides that were not coupled to KLH (data not shown).

The mapping results described in Table 2 were consistent with those obtained using aa 1 to 42 of IL-2 DNA (Fig. 3A). Therefore, on the basis of the results obtained with the synthetic peptides and DNA fragments described in Table 2 and Fig. 3, the region of IL-2 corresponding to aa 26 to 30 was subjected to site-specific mutagenesis, producing two constructs: one with a mutation at aa 27 (T27A) and another with three mutations at aa 26, 28, and 30 (S26G, S28G, S30G) (Fig. 5). When mice were injected with these two DNA constructs and infected with wt HSV-1, mice that were injected with IL-2 T27A DNA showed no sign of demyelination (Fig. 5, one mutation), while mice that were injected with the IL-2 DNA construct with three mutations in aa 26, 28, and 30 showed demyelination in their CNS (Fig. 5, three mutations). Thus, our results suggest that a single mutation in aa 27 of IL-2 blocked CNS demyelination in infected mice.

Quantitation of demyelination severity in infected mice. We observed that the severity of the HSV–IL-2–induced demyelination appeared to be the same as that in mice that received rIL-2 protein by a pump, full-length IL-2 DNA, DNA fragments corresponding to the CNS demyelination region of IL-2 DNA, full-length rIL-2 protein, or IL-2 synthetic peptides containing the STSSS sequence. To determine if the number of plaques and the size of plaques were different between these different groups, we counted the number and size of the plaques observed in the brains, spinal cords, and optic nerves of infected mice. The data are shown as the number of plaques and the area of demyelination per total stained section from Fig. 1 to 5. The number of plaques for mice

![Diagram](https://via.placeholder.com/150)
FIG 6 Severity of CNS demyelination following injection with different forms of IL-2 and infection with WT HSV-1 or control HSV–IL-2. The brains, spinal cords, and optic nerves of 5 mice in each treatment group for which the results are presented in Fig. 1 to 5 were sectioned, 30 sections per mouse per tissue were stained, and the size and the number of the demyelination plaques in the entire sections of the brains, spinal cords, and optic nerves were determined, as described in Materials and Methods. Data are presented as the number of plaques per section or the demyelination area in each section per the total number of sections stained using a total of 150 sections from 5 mice per group. (A) Numbers of plaques per brain section; (B) sizes of plaques per brain section; (C) numbers of plaques per spinal cord section; (D) sizes of plaques per spinal cord section; (E) numbers of plaques per optic nerve section; (F) sizes of plaques per optic nerve section.
that were injected with full-length rIL-2 protein was higher than that for mice in the other groups (Fig. 6A, C, and E). We also quantitated the area of demyelination (the size of the observed plaques) in mice whose results are presented in Fig. 1 to 5. Mice injected with different forms of IL-2 also had similar areas of demyelination (Fig. 6B, D, and F). Thus, our results suggest that, similar to HSV–IL-2, injection of mice with different forms of IL-2 induces a similar level of demyelination in ocularly infected mice.

DISCUSSION

Demyelinating diseases represent a spectrum of immune reactions in which, myelin, the fatty covering of nerve cell fibers in the brain, optic nerve, and spinal cord, is destroyed (29). Destruction of the myelin sheath has been associated with a number of diseases (30, 31), with multiple sclerosis (MS) being the most common condition of CNS inflammatory demyelination. The World Health Organization (WHO) estimates that over 2.5 million people globally suffer from MS, and according to the National Multiple Sclerosis Society, approximately 400,000 Americans have MS. The total economic impact of MS in the United States is estimated to be more than $28 billion per year. The available therapies, however, are not effective in all patients with MS. Thus, the development of new therapeutic and/or prophylactic drugs to control MS is critical. The cause of MS remains elusive. One hypothesis is that autoimmunity to antigens of the CNS is triggered by environmental factors, such as viral infection in genetically susceptible individuals, leading to destruction of the myelin (29, 32, 33).

Several lines of evidence suggest that IL-2 may be involved in CNS demyelination in MS (1–10). The presence of IL-2 is also associated with the disease state in experimental autoimmune encephalitis (EAE) (34–36) and following ocular infection of mice with HSV-1 (37–41). These observations suggest that, if IL-2 is involved, it alone may not be sufficient to initiate the observed pathology. Although evidence has accumulated that infectious agents, particularly viral agents, may be involved (42, 43); this, however, remains controversial (44–46). Previously, to show the involvement of higher levels of IL-2 in combination with viral infection in CNS demyelination, we constructed a recombinant HSV-1 strain constitutively expressing mIL-2, referred to as HSV–IL-2 (13). We have shown that injection of different strains of mice with the HSV–IL-2 recombinant resulted in CNS demyelination (17, 18). We have also found that injection of mice with a recombinant HSV-1 expressing IL-12p70 or injection of mice with IL-12p70 DNA blocks the CNS demyelination induced by the HSV–IL-2 recombinant (19, 20).

The HSV–IL-2 recombinant that we constructed and that we have shown induces CNS demyelination in ocularly infected mice is not a naturally occurring virus. Thus, the results obtained with the HSV–IL-2 recombinant may not directly support the hypothesis that elevated IL-2 levels in conjunction with viral infection contribute to CNS demyelination. Consequently, to rule out this possible ambiguity, we directly tested the potential role of elevation of IL-2 following infection with wild-type HSV-1 rather than infection with a recombinant HSV-1 strain expressing IL-2 (HSV–IL-2) in CNS demyelination. Evidence for the involvement of elevation of IL-2 in demyelination was observed using wt HSV-1 rather than HSV–IL-2. Demyelination was detected in the CNS of mice that received IL-2 by using rIL-2 protein, IL-2 DNA, or IL-2 peptides. Similar to our findings in our previous study (18), we detected CNS demyelination in BALB/c and C57BL/6 mouse strains. In addition, CNS demyelination was detected in both strains of mice infected with virulent wt HSV-1 strain McKrae and avirulent wt HSV-1 strain KOS. Overall, the degree of demyelination in brain, spinal cord, and optic nerve of infected mice was similar following injection of mice with IL-2 protein, IL-2 DNA, or IL-2 peptides. Moreover, this demyelination was similar to that in HSV–IL-2-infected mice (17–20).

The CNS pathology detected here is consistent with the published data concerning histologic analyses of specimens obtained from patients with MS at autopsy (47, 48), demyelination induced by mouse hepatitis virus (MHV) (49), and the EAE model of MS (47, 50). Analyses of the mechanisms by which the combination of the enhanced levels of IL-2 and viral infection elicits CNS demyelination suggest the possible role of IL-2 and viral infection in CNS pathology. Furthermore, our results suggest that full-length IL-2 is not required to induce CNS demyelination. In addition, the region of IL-2 that is involved in CNS demyelination resides within aa 26 to 30 of IL-2, and a single mutation (T27A) blocks HSV-1-induced CNS demyelination. These results have broad implications in terms of understanding the mechanisms by which elevated IL-2, which is common in autoimmune patients, can interact with environmental factors (in this case, HSV-1) to promote autoimmunity. They also suggest that selective targeting of IL-2 function may lay the basis for the development of therapies to rapidly control CNS demyelination in some patients.
