We previously reported that long-term rhesus cytomegalovirus (RhCMV) excretion in infected macaques was related to UL/b’ coding content. Acute biopsies of the inoculation sites from the previous study have now been analyzed to determine whether there were acute phenotypic predictors of long-term RhCMV infection. Only in animals displaying acute endothelial tropism and neutrophilic inflammation was RhCMV excretion detected. The results imply that vaccinating against these early viral determinants would significantly impede long-term RhCMV infection.
Human cytomegalovirus (HCMV) is a ubiquitous betaherpesvirus with adult seroprevalence rates of 50 -
>90% (5). The rate of congenital infection in the United States is ~0.7% (14), indicating that the preponderant
mechanism for spread of HCMV in the population occurs by the horizontal transmission. It is generally thought
that during primary infection HCMV replicates locally within epithelial and endothelial cells, and fibroblasts.
Local replication is followed by transmission to leukocytes for hematogenous spread of virions to multiple cell
types throughout the body, particularly sites of virus shedding (e.g., salivary glands, mammary glands,
genitourinary tract) (3, 21). Primary HCMV infection is mostly subclinical in an immune competent host.
However, HCMV establishes a lifelong latency following resolution of acute infection. Latent viral genomes can
reactivate to produce virus that can be transmitted to those most at-risk for HCMV infection, such as pregnant
women. The acute interactions between HCMV and a naïve individual are likely instrumental in defining the
number and tissue distribution of long-term HCMV-infected cells, the kinetics and specificities of adaptive
immune responses, and the frequency and magnitude of viral shedding. HCMV can infect multiple cell types in
vivo, including epithelial and endothelial cells, macrophages, and fibroblasts (21, 24). Since certain cell types
may assume a greater role in supporting primary HCMV replication, vaccine targeting of particular HCMV cell
tropism-determining proteins should limit local replication and greatly restrict the long-term pattern of HCMV
infection.

The phenotype of long-term RhCMV shedding in bodily fluids is dependent on the genotype of the strain of
RhCMV used for primary infection in naïve animals (18). Animals inoculated with RhCMV strains containing a
full-length UL/b' region (UCD52 and UCD59) persistently shed high titers of virus in saliva and urine similar to
the shedding in animals naturally exposed to wild-type (WT) RhCMV. Inoculation with the 68-1 strain of
RhCMV, which lack genes encoding proteins for epithelial/endothelial cell tropism and proteins potentially
involved in leukocyte chemoattraction (12, 15, 17, 18, 22), is characterized by pronounced attenuation of
shedding (18). This study was initiated to determine whether the patterns of acute infection predicted
differences in persistent infection.

To assess how coding content differences within the UL/b' region may alter primary RhCMV infection, early
virus-host interactions were analyzed in skin biopsies obtained from two previous studies (1, 19) in which
RhCMV-seronegative rhesus macaques (*Macaca mulatta*) had been inoculated subcutaneously with RhCMV 68-1 (N=3), RhCMV UCD52 (N=6), or UCD59 (N=1). Cytomegalic cells were present in all skin biopsies at 7 days post inoculation, accompanied by moderate infiltration of inflammatory cells admixed with variable degrees of tissue necrosis (Fig. 1). Both UCD52 and UCD59 induced a moderate inflammation composed predominantly of neutrophils (Fig. 1A; only UCD52 shown), while inflammation induced by RhCMV 68-1 was essentially mononuclear with negligible neutrophils at the site of inoculation (Fig. 1B). This particular phenotype of 68-1 has been observed in other studies (1).

The manifestations of HCMV infection depend on viral dissemination to multiple tissues, and viral tropism is an important determinant in viral spread within the infected host (24). Based on this, we asked whether inter-strain differences in the coding capacity of the UL/b′ region would predict inter-strain differences in cell tropism during acute RhCMV infection. Double immunohistochemistry was performed to identify the cell types supporting RhCMV infection, using antiserum for the RhCMV immediate-early (IE1) protein, and cell-specific markers for endothelial (CD31) and mesenchymal (vimentin) cells, and macrophages (CD68). The total numbers of all RhCMV and RhCMV double-labeled cells were counted, and the percentage of co-localization of the two markers was calculated by dividing the number of double-labeled cells by the number of RhCMV antigen-positive cells. The percentage of blood vessels containing RhCMV IE1 antigen-positive cells was calculated by dividing the number of RhCMV-positive blood vessels by the total number of blood vessels in the field. Only animals inoculated with UCD52 or UCD59 demonstrated RhCMV IE1 expression in endothelial cells with a frequency that was significantly greater than in 68-1-infected animals (P = 0.0357; Fig. 2A). Conversely, there was significant skewing of infectivity for fibroblasts in 68-1-infected animals compared to UCD52/UCD59-inoculated animals (P = 0.0167; Fig. 2B). UCD52/UCD59 infection of CD68+ macrophages was slightly higher than in 68-1-infected animals, although the difference did not reach statistical significance (P=0.12). Since RhCMV 68-1 does not encode RhUL128 and RhUL130, the mechanism for demonstrable infectivity of macrophages is not known since a functional HCMV UL128 complex is critical for efficient infection of human macrophages (24). *In vivo* infection of rhesus macrophages has been previously demonstrated in RhCMV-1-infected macaques (16), and infection of macrophages may be through a gB-mediated fusion.
To determine whether the acute pattern of infection with RhCMV was similar to the long-term reactivation of RhCMV, the cell types supporting reactivated RhCMV and the nature of the inflammatory infiltrate were analyzed in animals infected long-term with RhCMV and SIV. This analysis included two monkeys coinfected with RhCMV 68-1 and SIV from a previous study (23) and 100 historical cases of wild-type RhCMV (RhCMV-WT) reactivation in monkeys coinfected with SIV (the latter of which are summarized in Table 1). RhCMV-WT reactivation was found in almost every major organ system, the preponderance of which were equally distributed within the cardiovascular, pulmonary, and nervous compartments. Like the acute response following UCD52 and UCD59 inoculations, 88% of RhCMV-WT cases were noted for marked neutrophilic infiltrates (Fig. 1C). RhCMV-WT reactivations were in the context of simian AIDS in monkeys infected long-term with RhCMV-WT, indicating that RhCMV-WT reactivation during immune deficiency mirrored the histological pattern of acute infection with UCD52 and UCD59. Evidence of direct RhCMV-WT infection of endothelial cells was confirmed in four cases by the presence of inclusion bodies or immunohistochemistry in endothelial cells (Fig. 1E). In animals experimentally coinfected with RhCMV 68-1 and SIV, RhCMV reactivation was confirmed in the thymus and spinal cord of two animals euthanized at 38 and 53 weeks post primary RhCMV infection, respectively. The histopathologic pattern and cellular tropism of RhCMV reactivation reflected the patterns of acute RhCMV 68-1 infection (Fig. 1D). RhCMV 68-1 reactivation induced a predominantly mononuclear cell inflammation, and RhCMV immunoreactivity was confined to fibroblasts and macrophages with no evidence of endothelial cell infection (Fig. 1F).

Recruitment of neutrophils to the site of acute RhCMV infection and long-term reactivation is a novel finding and suggests that extravasated neutrophils may play a role in intra-host dissemination of progeny virions. This response is not unique to RhCMV. Neutrophilic infiltrates are often observed in the proximity of cytomegalic cells in tissues with HCMV disease (4, 6, 9, 13, 20). *in vitro* experiments have demonstrated that infected endothelial cells can transfer virions to neutrophils migrating through the endothelial layer, a process that is dependent on a functional UL128 complex of proteins (UL128, UL130, UL131, gH/gL) (2, 7, 8, 10, 11). Neutrophils may act as a “Trojan Horse” to facilitate virus dissemination from the primary site of infection to distal sites. This remains speculative and requires additional study.
In summary, there are differences in the acute patterns of infection between strains of RhCMV that differ in genetic coding content, with distinctions in cell tropism and the nature of the inflammatory response to viral infection. Differences in the phenotypes of acute infection were notably similar to the different phenotypes of AIDS-induced RhCMV reactivation. Based on pronounced differences in the long-term shedding between UCD52/UCD59 and 68-1 (18), one implication of preferential tropism for endothelial cells and/or recruitment of neutrophils from the periphery during acute infection is that long-term shedding patterns may be a downstream consequence of the earliest virus-host interactions during primary infection. Accordingly, vaccine strategies that target these earliest interactions should profoundly change the long-term virus-host relationship. The results of this current study suggest that inclusion of vaccine antigens targeting the UL128 complex of proteins should greatly inhibit the acute infection of endothelial and epithelial cells with commensurate changes in the long-term pattern of persistent infection.

We thank Andrew Miller, Charles Bailey, and the NEPRC histopathology core for helpful discussions and technical assistance. Grants from NIH (AI063356: PAB, DJD; RR000169: CNPRC; RR00168 and RR07000: NEPRC), and the Margaret Deterding Infectious Disease Research Support Fund (PAB) supported this study.

FIGURE LEGENDS

Fig. 1. Histopathologic features and immunostaining of skin biopsies collected from rhesus macaques experimentally inoculated with RhCMV UCD52 (A) or RhCMV 68-1 (B), RhCMV-WT reactivation in the context of SIV immunosuppression (C; jejunum, E; Pulmonary artery), and reactivated RhCMV 68-1 in SIV/RhCMV coinfected animals (D and F; spinal cord meninges). (A) and (C): Tissue sections from animals inoculated with RhCMV UCD52 or RhCMV-WT stained with H&E and RhCMV-IE1 IHC (insets) show diffuse regions of inflammation characterized by a large accumulation of neutrophils expanding the tissue and causing tissue necrosis. (B) and (D): In contrast to infection with RhCMV UCD52 and RhCMV-WT, acute (B) and chronic (D) inflammation in tissue sections collected from animals inoculated with RhCMV 68-1 lacked neutrophils and was composed predominantly of mononuclear cells. (E) Direct RhCMV-WT infection of endothelial cells during RhCMV reactivation, confirmed by RhCMV-IE1 immunoreactivity (inset; magenta) in endothelial cells (CD31 - brown) lining pulmonary arteries. (F) RhCMV 68-1 immunoreactivity (RhCMV IE-1 – magenta; inset) in fibroblasts (vimentin – brown). Large images 400X magnification; inset images 600X.

Fig. 2. Semi-quantitative spectral image analysis and immunophenotyping of RhCMV infected cells in skin biopsies collected from rhesus macaques experimentally inoculated with RhCMV UCD52 and UCD59 (circles), or RhCMV 68-1 (squares). Sections of the skin biopsies were co-immunolabeled against RhCMV-IE1 (brown) and endothelial cells (A; CD31), fibroblasts (B; vimentin), and macrophages (C; CD68) (Red). Quantification of the percentages (mean ± the standard error of the mean [SEM]) of RhCMV-infected blood vessels (A), fibroblasts (B), and macrophages (C) are presented. Double-labeled RhCMV-infected cells are indicted by arrows. Data were pooled from analysis of ten photomicrographs of one skin biopsy per animal. Statistical analysis was performed by using Mann-Whitney test by comparing RhCMV UCD infection with RhCMV 68-1 infection. Representative immunohistochemical images shown are from an animal inoculated with RhCMV UCD52 (images on left) and an animal RhCMV 68-1(images on right); 600X magnification. NS, P = 0.12.

<sup>a</sup> Case identification is based on histopathologic examination with observation of typical cytomegalovirus inclusion, and immunohistochemistry when available.

<sup>b</sup> GI: gastrointestinal

<sup>c</sup> 3 liver, 1 pancreas, 1 lacrimal gland, 1 adrenal, 5 oral cavity (tongue, salivary gland, and labial mucosa).

<sup>d</sup> numbers include those animals with RhCMV lesions observed in multiple organ systems; each lesion was separately counted. If ≥1 organ had a prominent neutrophilic infiltrate, that animal was classified as neutrophilic.

<sup>e</sup> Indicates neutrophils as the predominant type of inflammatory cell in the lesion.

<sup>f</sup> Usually superimposed by other opportunistic infections. Very few cytomegalic cells noted in these cases.
