Running title: IL-6 and acute seizures in viral encephalitis

Key words: Theiler’s murine encephalomyelitis virus, Seizures, Viral encephalitis, Picornavirus,
Innate immune response, Macrophages, Microglia, Inflammation

Abstract: 182 words
Text: 4,993 words
Abstract

Viral infections of the central nervous system (CNS) can trigger an anti-viral immune response, which initiates an inflammatory cascade to control viral replication and dissemination. The extent of the proinflammatory response in the CNS and the timing of the release of proinflammatory cytokines can lead to neuronal excitability. Tumor necrosis factor (TNF-α) and interleukin (IL)-6, two proinflammatory cytokines, have been linked to the development of acute seizures in Theiler’s murine encephalomyelitis virus-induced encephalitis. It is unclear the extent to which the infiltrating macrophages versus resident CNS cells, such as microglia, contribute to acute seizures, as both cell-types produce TNF-α and IL-6. In this study, we show following infection that a significantly higher number of microglia produce TNF-α compared to infiltrating macrophages. In contrast, infiltrating macrophages produced significantly more IL-6. Mice treated with minocycline or wogonin, both of which limit infiltration of immune cells into the CNS and their activation, have significantly fewer macrophages infiltrating the brain and significantly fewer mice have seizures. Therefore, our studies implicate infiltrating macrophages as an important source of IL-6 that contributes to the development of acute seizures.
Introduction

Although the etiology of seizures is largely unknown, infection of the central nervous system (CNS) is a significant risk factor for acquired epilepsy. There have been over 100 viruses implicated in the development of seizures in humans, including herpes viruses, Japanese encephalitis virus, Nipah virus, influenza viruses and non-polio picornaviruses [reviewed in (20)]. Therefore, due to the large number and types of viruses, identifying and deciphering the mechanism by which viral infection induces seizures has been challenging. For example, two members of the family Picornaviridae, enterovirus (EV) and parechovirus (PeV), have been shown to induce seizures in infected children; however, the available diagnostic tests for EVs do not detect PeVs (48; 49). A recent retrospective study, using pediatric cerebrospinal fluid samples previously screened for EV, demonstrated that the inclusion of a novel PeV-specific PCR assay led to a 31% increase in the detection of viruses causing virally-induced CNS symptoms and neonatal sepsis (51). Therefore, the role of viral infection in the induction of seizures has not been fully recognized, possibly due to the sensitivity and specificity of currently available viral diagnostic tests.

While there are many important, established animal models for the study of seizures/epilepsy, such as status epilepticus and trauma- and stroke-induced seizure models, these models do not mirror virally-induced seizures in humans (20). A significant difficulty with earlier viral models is that infected animals either die as a result of acute encephalitis and/or they do not have seizures following infection. Our laboratory has recently developed the first infection-driven animal model for epilepsy, called the Theiler’s murine encephalomyelitis virus (TMEV)-induced seizure model (24; 43). Approximately 50% of TMEV-infected C57BL/6
mice have seizures between days 3-10 post infection (p.i.) (24). C57BL/6 mice infected with
TMEV are able to clear the virus infected cells by about day 14 p.i. Furthermore, approximately
50% of the mice that had acute seizures go on to develop spontaneous seizures after an undefined
latent period (approximately two months), suggesting that a certain percentage of mice, as is seen
in humans, have an epilepsy-like phenotype following viral encephalitis (24; 43). Therefore, the
TMEV-induced seizure model is a viable model system to investigate the effect of an antiviral
immune response on the CNS that could potentially lead to seizures/epilepsy.
TMEV is a picornavirus that naturally infects mice (45; 46). TMEV infects a variety of
cells both in the CNS and in the periphery, including macrophages, dendritic cells, microglia,
and astrocytes (14; 32; 33; 41). Infection of cells with TMEV triggers a proinflammatory
response consisting of type I interferons, tumor necrosis factor (TNF)-α, interleukin (IL)-6, and
various chemokines (5; 15; 17; 21; 39; 44). The extent of the proinflammatory response in the
CNS and the timing of the release of proinflammatory cytokines such as IL-6 and TNF-α can
lead to neuronal excitability prior to the induction of the adaptive immune response, thereby
implicating a role for the innate immune system in the induction of seizures. Therefore, TMEV
infection has been used by our group to address how the innate immune system can have a
pivotal role in the development of seizures/epilepsy.
Our recent work has demonstrated an important role for microglia and macrophages, in
acute seizures (17; 21; 25). PCR arrays and antibody depletion studies were used to determine
that monocyte-derived cells were important in the development of acute seizures (21). In
addition, previous work from our laboratory, suggested that both resident cells and infiltrating
cells synergistically drove acute seizures possibly through the secretion of IL-6 (21). However,
it remains unclear as to the extent to which the infiltrating macrophages versus resident CNS
cells, such as microglia, contribute to acute seizures [reviewed in (20)]. Our rationale for defining what immune cells are involved in the induction of seizures is based on the potential of developing therapeutics that could be directed at these various cell-types, ultimately resulting in innovative approaches for the prevention and inhibition of seizures/epilepsy.

In our current study, we demonstrate that peripheral macrophages infiltrating the brains of TMEV-infected mice at the onset of seizures (day 3 p.i.) are important in the induction of seizures. In addition, we provide evidence that both microglia and macrophages synergistically contribute to the induction of seizures by differentially secreting TNF-α and IL-6. Importantly, administration of the anti-inflammatory compound wogonin was shown to inhibit the entry of peripheral macrophages into the CNS and was effective in the treatment of seizures in the TMEV-induced seizure model. These data provide proof-of-concept evidence for IL-6+ macrophages being involved in the development of seizures.
Materials and Methods

Animals

All animal experiments were in accordance with the guidelines prepared by the Committee on Care and Use of Laboratory Animals, Institute of Laboratory Animals Resources, National Research Council. C57BL/6 mice were obtained from the Jackson Laboratory (Bar Harbor, ME). Transgenic mice expressing green fluorescence protein (GFP) [C57BL/6CrSlc-Tg (ACTb-EGFP) OsbC14-Y01-FM131] were provided by Gerald Spangrude (University of Utah). GFP chimeric mice were generated as previously described (21). Briefly, donor bone marrow cells were obtained from euthanized mice that were at least 8 weeks old. The bone marrow cells were isolated from the tibias and femurs of donor mice by injecting phosphate buffered saline (PBS) containing 5% Cosmic calf serum (CCS) (Hyclone, Logan, UT). Red blood cells were lysed with ACK buffer [0.15 M ammonium chloride, 10 mM potassium bicarbonate (pH 7.2 to 7.4)] for 5 minutes and the remaining cells were washed in PBS and counted. For chimeric generation, 5 x 10^6 donor cells were intravenously (i.v.) injected into lethally irradiated (1200 rads) recipient mice (21). Mice were monitored for the 6 weeks required for engraftment before infection with TMEV. The success of the engraftment was determined by assessing, via flow cytometry, the levels of GFP^+ bone marrow cells obtained at termination of the experiment.

TMEV infection

Mice used were either 5- to 6-week-old C57BL/6 mice or 11- to 12-week-old GFP chimeric mice. Mice were anesthetized with isoflurane by inhalation and infected intracerebrally (i.c.) with 3 x 10^5 plaque-forming units (PFU) of the Daniels (DA) strain of
TMEV or mock-infected with PBS at a final volume of 20 μl per mouse. The DA strain of TMEV was propagated as previously described (53).

Peripheral mononuclear cell phenotyping

Peripheral blood was obtained from mice 5 days prior to TMEV infection and 48 hours after TMEV infection. Blood was obtained by submandibular bleed using Goldenrod lancets (MEDIpoint, Inc., Mineola, NY) and collected in BD vacutainer tubes (BD Bioscience, San Jose, CA). Whole blood was stained with the indicated antibodies for 30 minutes at room temperature and lysed for 20 minutes with BD whole blood lysis buffer (BD Bioscience). Cells were washed two times, fixed in 4% paraformaldehyde and analyzed by flow cytometry.

Brain mononuclear cell phenotyping

On day 3 p.i., mice were euthanized and perfused with PBS. Subsequently, cells were mechanically isolated from the brains and suspended in RPMI-1640 media (Mediatech, Herndon, VA) supplemented with 1% L-glutamine (Mediatech), 1% antibiotics (Mediatech), 50 μM 2-mercaptoethanol (Sigma-Aldrich, St. Louis, MO) and 10% CCS. Cells were further purified with Histopaque-1083 (Sigma). Cells were treated with Fc block (BD Bioscience), stained with the indicated anti-mouse antibodies for 30 minutes at 4°C [anti-CD45-v500, anti-CD11c-PerCP-Cy5.5, anti-CD3e-APC-Cy7, anti-CD86-PE-Cy7 (all obtained from BD Bioscience), anti-CD19-v450, anti-CD11b-APC, anti-MHC class II-PE, anti-NK1.1-PE (all obtained from eBioscience, San Diego, CA)], and analyzed by flow cytometry. Brain-derived cells were stained and analyzed individually for each mouse. Gating was determined by fluorescence-minus-one (FMO) with isotype matched immunoglobulin control. More specifically, FMO controls...
contained each antibody conjugate used in the experiment except one, with the addition of the appropriate isotype control for the excluded fluorochrome. This was performed for each fluorochrome using TMEV-infected brain samples. Live cells were determined by forward and side scatter fluorescence on a BD FACSCanto II (BD Bioscience). Cell sorting was performed at the University of Utah core facility using a FACSARia-II SORP (BD Bioscience).

Approximately $5 \times 10^4$ sorted-R2 cells were spun down onto slides using a Cytospin 2 (Shandon, Thermo Fisher Scientific, Waltham, MA), according to the manufacturer’s instructions. The slides were then air dried at room temperature for 5 minutes, incubated with acetone for 5 minutes, air dried and stained with hematoxylin (Harris Hematoxylin) and Eosin. Cell morphology of cells was determined by light microscopy. Flow cytometry data analysis was performed using FlowJo software (Tree Star, Inc., Ashland, OR).

**Direct intracellular cytokine staining (ICS)**

Direct ICS was performed as previously described (26). Briefly, mice were injected i.v. with 250 µg brefeldin A (Sigma) per mouse 6 hours prior to harvesting the brains. GFP chimeric mice were perfused with PBS, and brains were rapidly processed on ice. Extracellular surface staining for anti-CD11b-APC and 7-amino-actinomycin D (7-AAD) (BD Bioscience) was used for dead cell exclusion. Cells were then fixed and permeabilized with BD Cytofix/Cytoperm™ buffer (BD Bioscience), washed in BD Perm/Wash™ buffer (BD Bioscience) and stained with 0.5 µg/ml anti-IL-6-PE and anti-TNF-α-v450 (eBioscience) for 45 minutes at 4°C. Cells were washed with PBS containing 5% CCS prior to flow cytometry analysis.
Immunohistochemistry

Mice were euthanized between days 5-14 p.i. Animals were perfused with PBS, followed by 4% paraformaldehyde, and brains were harvested, divided into five coronal slabs, and embedded in paraffin. Multiple 4-µm-thick tissue sections were cut and mounted onto slides. Viral antigen positive cells were detected on paraffin sections using TMEV hyperimmune rabbit serum, as previously described (47; 53). GFP+ cells were detected with rabbit anti-GFP (Abcam, Cambridge, MA). Secondary fluorescent antibody was donkey anti-rabbit IgG-FITC (Jackson ImmunoResearch Laboratories, West Grove, PA). Fluorescence was detected on a Nikon Eclipse E800 microscope and analysis was performed using Image-Pro® Plus imaging software (Media Cybernetics, Inc., Bethesda, MD).

For IL-6 staining, sections were incubated with 3% normal donkey serum (Jackson ImmunoResearch Laboratories) for 30 minutes at room temperature, followed by incubation with rat (monoclonal) anti-mouse IL-6 unconjugated primary antibody (1:2,000 dilution in PBS; Invitrogen, San Diego, CA) overnight at 4°C. The next day, excess primary antibody was washed off with PBS and the sections were sequentially incubated for 30 minutes at room temperature first with 1% hydrogen peroxide to block, then with donkey anti-rat IgG biotin-SP-conjugated secondary antibody (1:2,500 dilution in PBS; Jackson ImmunoResearch Laboratories). The sections were visualized using the Vectastain ABC kit according to the manufacturer’s recommendations (Vector Laboratories Inc., Burlingame, CA) in conjunction with 3,3′-diaminobenzidine tetrahydrochloride (Sigma) and 0.01% hydrogen peroxide (Sigma) in PBS, followed by counterstaining with hematoxylin.

TNF-α staining was performed similarly to the IL-6 staining with slight modification. Briefly, an antigen retrieval step was performed by incubating slides in acid citrate buffer at 96ºC.
for 30 minutes. Additionally, the primary antibody was anti-TNF-α (1:200 dilution in PBS; Abcam) and the secondary antibody was donkey anti-rabbit IgG-biotin (1:1,500 dilution in PBS; Jackson ImmunoResearch).

Enumeration of IL-6 and TNF-α stained cells was performed in a blinded fashion with a light microscope, using one slide per brain and evaluating the section containing the hippocampal/dentate gyral region of the brain. Cytokine staining was enumerated in the following brain regions: dentate gyrus (DG), CA1, and CA2-CA3, all regions of the hippocampus; and the parietal cortex (PC). Using Image-Pro® Plus imaging software, these regions were outlined on images (10X magnification) of the section and both IL-6 and TNF-α stained cells were counted. A two-tailed t-test was used to compare groups and P<0.05 was considered significant.

Wogonin and minocycline treatment

Wogonin (5, 7-Dihydroxy-8-methoxy-2-phenyl-4H-chromen-4-one) (Sigma) was administered at 3 mg/kg once a day. Five- to 6-week-old C57BL/6 mice were injected intraperitoneally (i.p.) 24 hours prior to TMEV i.c. infection (3 x 10^5 PFU) and daily thereafter. Mice treated with vehicle [100% dimethyl sulfoxide (DMSO); Sigma] were infected and injected in parallel with the wogonin-treated mice. Mice were monitored daily for seizures through day 21 p.i. Minocycline (Sigma) was administered i.p. two times a day at 50 mg/kg starting 24 hours prior to infection with 3 x 10^5 PFU of TMEV and daily thereafter, as previously described (21).
Seizure scoring

The monitoring of seizure activity was performed as previously described (21). Briefly, mice were observed for 2 hours each day. Seizure activity was graded using the Racine scale: stage 1, mouth and facial movements; stage 2, head nodding; stage 3, forelimb clonus; stage 4, rearing; stage 5, rearing and falling (4; 37).
Results

Immune cells in peripheral blood in TMEV-infected mice

To determine the numbers of specific mononuclear cells in the peripheral blood of individual TMEV-infected mice compared to uninfected mice, blood was collected 5 days prior to and 48 hours after infection. The numbers of mononuclear cells expressing markers for monocytes/macrophages (CD45$^+$ CD11b$^+$), dendritic cells (CD45$^+$ CD11c$^+$), T (CD45$^+$ CD3$^+$) and B (CD45$^+$ CD19$^+$) cells were determined by flow cytometry. The numbers of each cell-type except dendritic cells was significantly higher in the peripheral blood following infection (48 hours p.i.), compared to baseline (5 days prior to infection) (Table I). Analysis of CD45$^+$ CD11b$^+$ monocytes/macrophages in the periphery of individual TMEV-infected mice (Figure 1) clearly demonstrated a significant increase in peripheral monocytes/macrophages for each mouse following infection (Figure 1B, P<0.05).

Phenotypic analysis of immune cells infiltrating the brains of TMEV-infected mice

Previous work from our laboratory suggested that monocytes/macrophages were important in the induction of acute seizures (21). To determine if the increase in number of peripheral blood mononuclear cells reflected what was occurring in the brain, we obtained brains from either mock- or TMEV-infected mice 3 days p.i. (a time point just prior to the onset of seizures). Quantification of cells isolated from the brains of infected mice in comparison to cells isolated from the brains of mock-infected mice showed a marked increase in the numbers of cells expressing CD11b (infiltrating macrophages, microglia) (Figure 2A, P<0.05). CD45 was deliberately not used in the initial CD11b analysis as a means of including the resident...
monocyte-derived CNS cells (microglia) in addition to infiltrating macrophages in the analysis, thereby taking a more comprehensive approach to determine if there was an increase in CD11b expression. In contrast to the CD11b population, at 72 hours p.i. few if any B (CD45+ CD19+) (Figure 2B), T (CD45+ CD3+) (Figure 2C), and natural killer (CD45+ NK1.1+) (Figure 2D) cells were detected. In addition, phenotypic analysis of markers of activation of CD11b+ monocyte-derived cells showed a significant increase in major histocompatibility complex (MHC) class II and CD86 expression on the CD11b+ cell population isolated from the brains of TMEV-infected mice, compared to mock-infected mice (Figure 3, P<0.05). These results suggest that peripheral macrophages infiltrating the brain are involved in the development of acute seizures, and, importantly, that the peripheral blood does not mirror what is occurring in the CNS.

Resident microglia versus infiltrating macrophages

Both microglia and macrophages are derived from myeloid progenitor cells, and, therefore, express similar cell surface markers (12). To determine whether resident microglia, instead of infiltrating macrophages, could be the CD11b+ cells found in the brains of TMEV-infected mice, phenotypic markers were used to differentiate microglia from macrophages; microglia have low to intermediate expression of CD45 and high CD11b expression, whereas macrophages express high levels of both CD45 and CD11b on the cell surface (10; 40). Cells from TMEV-infected mouse brain had macrophages (CD45hi CD11b+) (Figure 4A, R2) infiltrating the brain versus mock-infected mouse brain cells. The number of macrophages (CD45hi CD11b+) (Figure 4B, R2) was significantly higher (P<0.05) in TMEV-infected mice (39.3 ± 9.1) in comparison to mock-infected mice (2.0 ± 0.8). The number of microglia (CD45lo/int CD11b+) (Figure 4B, R1) was lower in the TMEV-infected mice (14.3 ± 3.2)
compared to mock-infected mice (25.9 ± 3.5), but this difference was not statistically significant. To verify CD45\(^{hi}\) CD11b\(^{+}\) cells were monocyte-derived cells and not neutrophils, the CD45\(^{hi}\) CD11b\(^{+}\) (R2) cells expressing GR-1 protein were sorted, spun down onto a slide, and stained with Hematoxylin and Eosin (Figure 4C, D). The R2-sorted population was predominately monocytes and eosinophils, not cells with segmented nuclei (representative of neutrophils) (Figure 4D).

GFP chimeric mice were used to confirm that macrophages are infiltrating the brains of TMEV-infected mice and to exclude the possibility that microglia, expressing high levels of CD45 upon activation following infection, could account for the higher number of CD45\(^{hi}\) CD11b\(^{+}\) cells present in the brains of TMEV-infected mice (Figure 4, R2). GFP chimeric mice were generated by adoptive transfer of GFP\(^{+}\) bone marrow cells into C57BL/6 lethally-irradiated mice (7; 10; 13; 18; 30). Although the chimeric mice are older than the wild-type mice, previous work from our laboratory has demonstrated that age does not have an effect on the number of mice having seizures after TMEV-infection (21). GFP chimeric mice were infected with TMEV and phenotypic analysis was used to quantify the numbers of CD11c\(^{-}\) CD11b\(^{+}\) GFP\(^{-}\) cells (Figure 5). Flow cytometric differentiation of microglia from macrophages confirmed that the R1 resident microglia population (CD45\(^{lo/int}\) CD11b\(^{+}\)) was the CD11c\(^{-}\) CD11b\(^{+}\) GFP\(^{-}\) cells and the R2 infiltrating macrophage population (CD45\(^{hi}\) CD11b\(^{+}\)) was the CD11c\(^{-}\) CD11b\(^{+}\) GFP\(^{+}\) cells (Figure 5A). The brains from TMEV-infected mice had a significantly higher number of GFP\(^{+}\) cells, i.e. macrophages, (53.42 ± 18.7) in comparison to brains from mock-infected chimeric mice (9.5 ± 3.1) (Figure 5B, C, P<0.005). The number of GFP\(^{-}\) cells (microglia) quantified from the brains of TMEV-infected mice (46 ± 18.6) was significantly lower in comparison to mock-
infected mice (87.5 ± 4.8) (Figure 5C, P<0.005). Taken together, these results demonstrate that macrophages are the dominant cell-type infiltrating the brain during acute seizures.

Link between the number of mice having seizures and macrophages infiltrating the brain

To establish a link between macrophages infiltrating the brain and mice having seizures, GFP chimeric mice were infected with TMEV and monitored daily for seizures. Mice were sacrificed between days 5-14 p.i. and brain sections were stained for GFP (infiltrating cells) (Figure 6A). The GFP+ macrophages were quantified in the right hemisphere of the brains (site of injection) in a blinded fashion using Image-Pro Plus (Figure 6B). Tissue sections from both mice having seizures and mice not having seizures were equally split between day 5 and day 14 for this analysis. There was a significant difference in the number of GFP+ macrophages in the brains of mice that had seizures (n=6) versus mice that did not have seizures (n=4) (Figure 6B, P<0.05). In support of previous work (22), the number of viral antigen-positive cells found to be present in the brains of these mice was markedly increased in mice with seizures (1541 ± 654) compared to mice without seizures (144 ± 87). These results show a link between macrophages infiltrating the brain and animals experiencing a seizure.

Microglial cell versus macrophage cytokine production

Both TNF-α and IL-6 cause the amplification of proinflammatory signals within the CNS, which can lead to neuronal excitability and its related neuropathology (2; 16; 21; 36). To determine if microglia and/or macrophages produce these cytokines following infection, cells were isolated from the brains of mock- and TMEV-infected GFP chimeric mice on day 3 p.i. and ex vivo ICS staining was performed for TNF-α and IL-6 (Figure 7). None of the mice at day 3
p.i. were observed to have seizures, thereby not allowing for a comparison between mice that had
seizures and mice that did not have seizures. However, we could compare the cytokine levels
between resident microglia and infiltrating macrophages. Significantly higher numbers of
microglia (GFP−) were positive for TNF-α versus macrophages (GFP+) (Figure 7A, P<0.05).
Conversely, macrophages (GFP+) represented significantly higher numbers of cells positive for
IL-6 in comparison to microglia (GFP−) (Figure 7B, P<0.05). Furthermore, R1 and R2 cells
from TMEV-infected wild-type mice were stained for IL-6 and the R2 infiltrating macrophages
had a markedly higher number of IL-6+ cells than the R1 resident microglia cells (data not
shown), thereby supporting the GFP chimeric cytokine results (Figure 7). To confirm that
TMEV-infected mice experiencing seizures had more IL-6+ and TNF-α+ cells in the brains
compared to controls and mice not experiencing seizures, IHC staining was performed (Tables II
and III, Figures 8 and 9). There was a significant increase (P<0.05) in the number of IL-6+ cells
in the CA2-CA3 region of the hippocampus and PC region in mice that had seizures (Table II,
Figure 8). Conversely, the DG and CA1 regions of the hippocampus had a significantly higher
(P<0.05) number of TNF-α+ cells (Table III, Figure 9). Taken together, microglia make up the
majority of the TNF-α producing cells, and infiltrating macrophages make up the majority of the
IL-6 producing cells, which suggests that microglia and macrophages synergistically produce
proinflammatory cytokines that potentially lead to the induction of acute seizures.

Inhibition of macrophage infiltration

The natural root extract, wogonin, and the antibiotic minocycline were used to inhibit
macrophage activity. Wogonin has antioxidant properties and can induce apoptosis of cells that
have been previously sensitized by TNF-α (9; 42). Minocycline has anti-inflammatory
properties leading to lower CNS excitability (38). Flow cytometry was performed on cells isolated, on day 3 p.i., from the brains of TMEV-infected C57BL/6 mice, which were treated with vehicle (DMSO), wogonin, or minocycline (Figure 10). The number of microglial cells (R1) was not statistically different between the three treatment groups, but the number of infiltrating macrophages (R2) was significantly lower in the wogonin- (16.4%) and minocycline- (13.6%) treated groups versus the vehicle-treated group (32.1%) (Figure 10B, P<0.05). Both wogonin and minocycline inhibited the infiltration of macrophages by approximately 2-fold.

**Fewer mice experience seizures when treated with wogonin**

Previous work by our laboratory using the TMEV-induced seizure model demonstrated that minocycline was able to significantly inhibit the number of mice having seizures by approximately half (21; 23). Therefore, to determine if wogonin had a similar effect as minocycline on the number of mice having seizures, TMEV-infected C57BL/6 mice were treated with either vehicle (DMSO) or wogonin (3 mg/kg/day) and monitored daily for seizures. Mice treated with wogonin had significantly fewer seizures (35%) than vehicle-treated mice (63%) (Figure 11, P<0.05). This was about a 2-fold reduction in the number of mice having seizures, similar to the 2-fold reduction in the number of mice having seizures following minocycline treatment, and similar to the 2-fold reduction in the number of infiltrating macrophages following treatment with wogonin. These results indicate that the inhibition of macrophages by 2-fold could potentially have a therapeutic benefit.
The role of the immune system in seizures/epilepsy is largely unknown; however, evidence of proinflammatory mechanisms being involved in seizures/epilepsy have been described in experimental models [reviewed in (50)]. Previous studies performed in our TMEV-induced seizure model demonstrated that the inhibition of monocytes resulted in significantly fewer mice experiencing seizures; therefore, monocyte-derived cells (microglia and macrophages) were contributing to the induction of seizures [reviewed in (20)]. In this study we found a significantly higher number of macrophages in the brains of TMEV-infected mice that had seizures in comparison to mock-infected mice. Furthermore, treatment with anti-inflammatory compounds, wogonin and minocycline, significantly reduced the number of macrophages infiltrating the brain. Therefore, infiltrating macrophages are driving acute seizures during viral infection, likely through IL-6 production.

Various cell-types of the innate immune system have been hypothesized to be involved in the induction of seizures, including monocytes and neutrophils (8). Mononuclear cell infiltration in epilepsy has been described in mesial temporal lobe epilepsy (TLE) patients; using the pan mononuclear cell marker anti-CD45 antibody, a higher number of mononuclear cells (CD45⁺) were observed in the hippocampus of mesial TLE patients compared to control non-mesial TLE stained tissue sections (27; 52). This suggests widespread activation of the innate immune system in epileptic patients (27; 52). Consistent with these reports, in the present study, cells isolated from TMEV-infected mouse brains had a significantly higher number of mononuclear cells (CD45⁺) (data not shown). Furthermore, phenotypic analyses of TMEV-infected mouse
brain cells clearly showed macrophages (CD45<sup>hi</sup> CD11b<sup>+</sup>) as being the major mononuclear cell population infiltrating the brain at day 3 p.i. (Figures 2 and 4).

We examined the role of neutrophils in our previous studies by depleting neutrophils through the administration of the anti-granulocyte-differentiation antigen-1 (Gr-1) antibody (clone RB6-8C5) (21). We found that there was no significant effect on the number of mice having seizures (21). However, a study using a different seizure model identified infiltrating neutrophils in the brains of mice that had seizures when examined at greater than day 7 post-seizure induction (52). The anti-GR-1 antibody (clone RB6-8C5) has been shown to be nonspecific for neutrophils (6); therefore we verified that the majority of cells in the CD45<sup>hi</sup> CD11b<sup>+</sup> R2 population were monocytes, as opposed to neutrophils, by sorting the R2 population of cells and performing Hematoxylin and Eosin staining (Figure 4C, D). Taken together, these results suggest that neutrophils could be involved in the development of epilepsy, but not in the induction of acute seizures during viral encephalitis (8; 21; 52).

Through the use of GFP chimeric mice, we demonstrated that monocyte-derived CD11b<sup>+</sup> GFP<sup>+</sup> cells were present in the brain following TMEV infection (Figure 5B, C). In turn, we showed that these GFP<sup>+</sup> cells were infiltrating macrophages (Figure 5A). Further analysis of these TMEV-infected GFP chimeric mice showed that those mice that experienced seizures had a significantly higher number of GFP<sup>+</sup> cells (infiltrating macrophages) in the brain tissue sections versus TMEV-infected GFP chimeric mice that did not have seizures (Figure 6). Therefore, these results demonstrate a link between macrophage infiltration and mice experiencing seizures.

Activated microglia and macrophages release inflammatory cytokines, prostaglandins, and nitric oxide possibly leading to neuronal excitability and neuronal damage (31). In our study, TMEV-infected mice had significantly higher expression of MHC class II and CD86 on
monocytes, indicating that microglia and macrophages were highly activated (Figure 3).

Furthermore, in our model, fewer IL-6-deficient and TNF receptor 1 knockout mice infected with TMEV experienced seizures in comparison to wild-type infected mice, implicating both IL-6 and TNF-α in the pathogenesis of seizures (17; 21; 23). However, the pathological changes in mice experiencing seizures were consistent, regardless of the mouse genetic background, suggesting that the amount, timing, and the type of cell producing these cytokines could be factors in cytokines having a pathogenic role in viral encephalitis-induced seizures. For example, exercise-induced IL-6 production in the CNS has been shown to decrease apoptosis of dentate granule neurons in the hippocampus after chemical treatment in mice that exercised in comparison to mice that did not exercise (11). Conversely, overexpression of IL-6, a key activator of astrocytes and microglia, above a theoretical threshold can lead to immunopathology, including severe motor impairments, in various models (3; 19). Single cell analysis of brain cells demonstrated that both microglia and macrophages produced TNF-α and IL-6 in TMEV-infected mice (Figure 7). However, significantly more infiltrating macrophages were IL-6+ versus resident microglia (Figure 7). Conversely, resident microglia had a significantly higher number of TNF-α+ cells versus infiltrating macrophages (Figure 7). Taken together, the increase in IL-6 producing macrophages infiltrating the brain, in conjunction with resident microglia producing TNF-α, could be elevating the levels of proinflammatory cytokines above a protective/reparative threshold to a pathological state, causing neuronal excitability, damage, and seizures. Once the threshold to a pathological state is crossed during viral encephalitis, the mice will experience seizures and have similar pathology due to the anti-viral immune response, thereby accounting for the observation that the immunopathology in the mice that have seizures is similar between mice regardless of the viral titer (22). However, the role of
Therefore, further experiments are needed to characterize the role of IL-6 and TNF-α in the induction of seizures.

The inhibition of seizures with anti-inflammatory compounds has provided indirect experimental evidence that inflammation is important in the induction of seizures (1; 28; 29). For example, administration of minocycline prior to kainic acid (KA)-induced status epilepticus significantly decreased the number of activated microglia in the hippocampus (1). Furthermore, administration of minocycline to TMEV-infected mice resulted in significantly fewer mice having seizures (21; 23). However, these studies did not determine the effect of minocycline on peripheral macrophages (1; 21; 23). In this study, minocycline administered to TMEV-infected mice significantly reduced the number of macrophages infiltrating the brains by approximately 2-fold (Figure 10). Another potential anti-convulsive compound, wogonin (34), was administering to TMEV-infected mice. Similar to minocycline, wogonin-treatment resulted in an approximately 2-fold decrease in infiltrating macrophages (Figure 10) and significantly fewer mice experiencing seizures (Figure 11). Taken together, these results link the number of infiltrating macrophages to the number of mice experiencing seizures. Unfortunately, a potential side-effect of an anti-inflammatory compound is the suppression of the immune response to a pathogen. This could leave the host susceptible to viral persistence and/or opportunistic infection. However, in our study, immunohistochemical staining (on days 14 and 21 p.i.) for TMEV on brain tissue sections of vehicle-treated and wogonin-treated TMEV-infected mice showed no difference in the number of cells containing TMEV antigen (data not shown). Whether wogonin targets activated TMEV-specific T cells is not known, however, due to the low concentration of wogonin administered, a certain percentage of activated TMEV-specific T cells
may escape targeting and be sufficient for viral clearance. These results are in agreement with previous reports that demonstrated wogonin specifically targeting activated cells and not resting immune cells (9; 35). Therefore, wogonin-treated mice are able to clear TMEV, even though wogonin inhibits activated macrophages.

In conclusion, these results demonstrate a role for infiltrating macrophages as a pathological mechanism in the induction of acute seizures, possibly through secretion of IL-6 in the CNS. Furthermore, administering anti-inflammatory compounds, such as wogonin, in the treatment of seizures could provide a non-toxic therapeutic approach for seizures/epilepsy, and work is currently underway to determine the mechanism of action that wogonin could be employing on IL-6 producing cells to inhibit seizures in the CNS.

(I-L) C57BL/6 IL-6-/- mouse. Arrows point to IL-6+ cells. Pictures were imaged at 20x magnification. Control (IL-6-/-) TMEV-infected mice were stained in conjunction with the experimental tissue sections. Insets are 40x magnification. CA, Cornu Ammonis; DG, dentate gyrus; PC, parietal cortex.
Figure 9. TNF-α+ cells in GFP chimeric mice. Representative hippocampal tissue sections immunohistochemically stained for TNF-α. All representative brain tissue sections were obtained from TMEV-infected mice at day 7 p.i. (A-D) Mouse that did not experience seizures. (E-H) Mouse that experienced seizures. (I-L) Brain tissue section from mouse that experienced seizures with no primary antibody (Ab). Brown color indicates TNF-α staining. Pictures were imaged at 20x magnification. Control (no primary Ab) TMEV-infected mice were stained in conjunction with the experimental tissue sections. Insets are 40x magnification. CA, Cornu Ammonis; DG, dentate gyrus; PC, parietal cortex.

Figure 10. TMEV-infected C57BL/6 mice treated with minocycline and wogonin have a significantly lower number of infiltrating macrophages in the brain compared to vehicle-treated mice. A. Representative flow cytometry plots of cells obtained on day 3 p.i. from the brains of TMEV-infected mice treated with vehicle (DMSO), wogonin or minocycline. Microglial cells are CD45lo/int CD11b+ (R1). Macrophages are CD45hi CD11b+ (R2). B. No significant differences in the numbers of microglia (R1) were detected. Minocycline- and wogonin-treated mice had significantly fewer macrophages (R2) infiltrating into the brain, compared to vehicle-treated mice. Data is presented as the mean + SEM with 5 mice per group. *P<0.05, Student’s paired t test.

Figure 11. Seizure (Racine scale stages 3 to 5) frequency in wogonin- and vehicle-treated mice. C57BL/6 mice infected with TMEV were treated, as described in the Materials and Methods, with either vehicle (DMSO) or wogonin and monitored for seizures. Wogonin-treated mice had significantly fewer seizures (35%) than vehicle-treated mice (63%). ‡P<0.05, chi-square test.
The total number of mice infected (N) is shown above each individual bar of the graph. The percentage of mice was determined by number of mice with seizures/total number of mice infected for each group x 100.
