ABSTRACT

Following reactivation from latency, there are two distinct steps in the spread of herpes simplex virus (HSV) from infected neurons to epithelial cells: i) anterograde axonal transport of virus particles from neuron cell bodies to axon tips and ii) exocytosis and spread of extracellular virions across cell junctions into adjacent epithelial cells. HSV heterodimeric glycoprotein gE/gI is important for anterograde axonal transport and gE/gI cytoplasmic domains play important roles in sorting of virus particles into axons. However, the roles of the large (~400 residue) gE/gI extracellular (ET) domains in both axonal transport and neuron-to-epithelial cell spread have not been characterized. Two gE mutants: gE-277 and gE-348 contain small insertions in the gE ET domain, fold normally, form gE/gI heterodimers and are incorporated into virions. Both gE-277 and gE-348 did not function in anterograde axonal transport, there was markedly reduced numbers of viral capsids and glycoproteins, compared with wild type HSV. The defects in axonal transport were manifest in neuronal cell bodies involving missorting of HSV capsids before entry into proximal axons. Although there were diminished numbers of mutant gE-348 capsids and glycoproteins in distal axons, there was efficient spread to adjacent epithelial cells, similar to wild type HSV. By contrast, virus particles produced by HSV gE-277 spread poorly to epithelial cells, despite similar numbers of virus particles as gE-348. These results genetically separate the two steps in HSV spread from neurons to epithelial cells and demonstrate that the gE/gI ET domains functions in both processes.

IMPORTANCE

An essential phase of the life cycle of herpes simplex virus (HSV) and other α-herpesviruses is the capacity to reactivate from latency then spread from infected neurons to epithelial tissues. This spread involves at least two steps: i) anterograde transport to axon tips, followed by ii) exocytosis and extracellular spread from axons to epithelial cells. HSV gE/gI is a glycoprotein that facilitates this virus spread, although by poorly understood mechanisms. Here, we show that the extracellular (ET) domains of gE/gI promote the sorting of viral structural proteins into proximal axons to begin axonal transport. However, the gE/gI ET domains also
participate in the extracellular spread from axon tips across cell junctions to epithelial cells.

Understanding the molecular mechanisms involved in gE/gI-mediated sorting of virus particles into axons and extracellular spread to adjacent cells is fundamentally important in terms of identifying novel targets to reduce α-herpesvirus disease.

INTRODUCTION

α-herpesviruses such as HSV and varicella zoster virus (VZV) have evolved specialized mechanisms enabling virus spread in epithelial and neuronal tissues. Primary infection involves entry into skin or mucosal epithelial cells followed by rapid virus spread between these cells. During this phase of virus replication and spread, viruses enter sensory neurons by fusion of the virion envelope with neuronal membranes so that capsids are delivered into the cytoplasm. Capsids undergo retrograde axonal transport on microtubules toward neuronal cell bodies or nuclei in ganglia where latency is established. Later, following stimulation of neurons, latent virus reacti\n
Capsids arriving at axon termini become enveloped with membranes containing viral glycoproteins and enveloped virions escape into the extracellular space by exocytic mechanisms. Most enveloped particles outside cells remain attached on neuron surfaces. These particles are likely to be in direct contact with epithelial cells that form cell-cell junctions with neurons. The subsequent entry of viruses into epithelial cells involves fusion of the virion envelope with epithelial cell membranes. Once inside highly permissive epithelial cells, viruses can replicate to high titers and rapidly spread causing local ulceration and amplifying virus that can spread to other hosts.
HSV expresses two membrane proteins, gE/gI and US9, which are key to understanding the combined processes of anterograde axonal transport and extracellular cell-to-cell spread (reviewed in [2]). gE/gI is a heterodimer formed from two polypeptides gE and gI, the heterodimer forms cotranslationally or very shortly after synthesis, both polypeptides are required for ER export, all (or the vast majority) of gE in HSV-infected cells and virions bound by gI, and both gE/gI are required for cell-to-cell spread [9-13]. Thus, we consider HSV gE/gI one protein. gE and gI each contain ~400 a.a. extracellular (ET) domains and ~100 a.a. cytoplasmic (CT) domains. HSV and the related pig pseudorabies virus (PRV) gE/gI CT domains encompass multiple membrane trafficking motifs including acidic clusters, di-leucine and tyrosine motifs that cause the protein to extensively localize to the trans-Golgi network (TGN) [14-19]. In polarized epithelial cells HSV gE/gI-null mutants show markedly reduced cell-to-cell spread and within the corneal epithelium HSV spread was ~5% compared with wild type HSV [11,15,20]. Defects in cell-to-cell spread of gE/gI mutants are the outcome of reduced accumulation of HSV at cell-cell junctions [13]. This sorting of virions to cell-cell junctions requires the gE CT domain, suggesting that gE/gI must localize to the TGN (through TGN sorting motifs) in order to direct egress of HSV particles to epithelial cell junctions. Similar types of gE/gI-mediated sorting may also occur in neurons. HSV and PRV US9 proteins are different in structure from gE/gI molecules. US9 proteins are type II membrane proteins, tail-anchored, with no significant extracellular domains, but, like gEgI, contain CT domains that contain TGN-localization motifs [21-23]. HSV US9 plays no role in spread between epithelial cells but specifically functions in neurons and apparently only in anterograde axonal transport [22]. HSV and PRV gE-, gI- and US9- null mutants all display significant defects in the transport of capsids, glycoproteins and enveloped virions in neuronal axons [24-29]. These studies fit well with highly reduced spread of HSV and PRV gE/gI and US9 mutants within the nervous system and from sensory ganglia to corneal epithelium [17,22,30-33]. HSV gE/gI and US9 possess overlapping or additive effects in anterograde axonal transport, mutants lacking one of gE, gI or US9 displayed significantly reduced transport of capsids and glycoproteins in
more distal sections of axons (50-90%), but deletion of both gE and US9 produced near zero levels of capsids and glycoproteins even in proximal axons [27,28]. PRV appears different in this regard, gE/gI contributes to efficient anterograde transport but US9 is essential for anterograde transport [29,34]. As with sorting of virions in epithelial cells, HSV and PRV gE, gI and US9 CT domain TGN sorting motifs contribute to anterograde axonal transport [16,17,21,27,32].

Observations that HSV gE/gI and US9 can promote the anterograde axonal transport of unenveloped capsids, which are not obviously membrane associated, provided some clues as to how gE/gI and US9 (both membrane proteins) might function [6,27,28]. We proposed the “Loading hypothesis” that suggests that HSV gE/gI and US9 promote TGN accumulation of capsids and membrane vesicles containing glycoproteins and enveloped virions in neuron cell bodies [6,27]. TGN-like membranes are likely sites of loading of virus structural components onto kinesin motors for subsequent transport into axons. gE/gI and other HSV glycoproteins can interact with tegument proteins that, in turn, interact with capsids (reviewed in [2]). Thus, by promoting the sorting of viral structural components including tegument-coated capsids to TGN-like membranes, gE/gI and US9 might enhance loading onto kinesin motors. Consistent with this hypothesis, an HSV gE-/US9- double mutant did not transport glycoproteins or capsids into proximal axons and, instead, accumulated HSV structural proteins in cell bodies [28].

The second step in α-herpesvirus spread from neurons to epithelial cells involves exocytosis of enveloped virus particles at axon tips followed by entry into adjacent epithelial cells. The model described above suggests that enveloped virions are shed onto the surfaces of axons, specifically at neuron-epithelial cell junctions so that virus particles are directly in contact with epithelial cells. Supporting this model, the PRV membrane glycoprotein gB is not required for anterograde axonal transport, but is essential for virus spread from neurons to adjacent cells [35]. α-herpesvirus gB molecules are the membrane fusion proteins required for virus entry (reviewed in [36]. These results demonstrate the requirement for a viral fusion machinery to promote entry of extracellular virions into epithelial cells.
While the CT domains of gE/gI clearly play important roles in anterograde axonal transport and cell-to-cell spread, the gE/gI heterodimer has ET domains that constitute ~80% of the protein. There is no information on how the gE/gI ET domains function in either axonal transport or extracellular virus spread, largely related to difficulties in truncating the N-terminal domains while retaining any semblance of ER folding and export and heterodimer formation. During axonal transport, the gE/gI ET domains are present within the lumen of vesicles and, thus, it is not clear how these domains would affect interactions with kinesin motors, adaptors or other cytoplasmic proteins. However, once virions are in the extracellular space, gE/gI ET domains are exposed on virion surfaces and might play a role in neuron-to-epithelial cell spread. Here, we characterized two HSV gE ET domain mutants gE-277 and gE-348 in neurons for their capacity to mediate axonal transport and extracellular spread to epithelial cells. Mutants 277 and 348 were both defective in anterograde transport, the numbers of HSV capsids and gB-containing vesicles in distal axons were reduced to numbers similar to that of a gE-null mutant. Surprisingly, despite reduced numbers of virus particles in distal axons, HSV gE-348 could spread normally (as well as wild type HSV) from neurons to epithelial cells. By contrast, HSV gE-277 was unable to mediate this spread.

MATERIALS AND METHODS

Cells and viruses. Vero and HaCaT cells were grown in Dulbecco’s modified Eagle’s medium (D-MEM) containing 10% fetal bovine serum. Vero cells were used to propagate and titer HSV. HaCaT cells are a spontaneously transformed keratinocyte cell line [15,37]. HSV F-gEβ is a gE-null mutant that was described [11]. F-BAC gE-256-5 (here denoted gE-256), F-BAC gE-277, and F-BAC gE-348-4 (here denoted gE-348) contain 4-5 amino acid insertions in the extracellular domain of gE [20]. These HSV have BAC sequences inserted into the HSV thymidine kinase (TK) gene [38]. For replication of these mutant viruses in neurons, the TK genes was repaired by cotransfecting Vero cells with viral DNAs extracted from cytoplasmic nucleocapsids [39] and a plasmid, pTK173, containing the HSV TK gene [40] using the CaPO4 transfection method [41]. Viruses derived from these transfections were plated on 143-TK- cells,
which were treated with 0.1 mM hypoxanthine, 1 μM aminopterin, and 40 μM thymidine (HAT media) to select for TK+ viruses [42]. TK+ viruses were plaque purified in 3 rounds using HAT selection then the presence of the mutations verified by PCR and by immunoprecipitation with a tk-specific antibody (not shown). The TK+ viruses produced were denoted HSV gE-256, gE-277, and gE-348. These mutant viruses were repaired for gE expression by preparing viral DNA and cotransfecting Vero cells with this DNA and a plasmid (pUC-US7/8) containing the wild type gE gene [19]. The viruses produced by this transfection were screened using HaCaT cells, selecting large plaques that were then plaque purified 3 times. The repaired viruses: HSV gE-277R and gE-348R were analyzed by PCR to confirm the wild type gE sequences.

**Neuronal cell cultures.** Superior cervical ganglia (SCG) were dissected from day 18 embryos removed from pregnant Sprague-Dawley rats and dissociated by incubation in 0.25% trypsin in Hibernate A media lacking calcium (Brainbits, LLC) at 37°C for 10 min. Ganglia were then incubated in 1% soy bean trypsin inhibitor in Hibernate A-Ca for 5 min at 37°C then transferred into Neurobasal media supplemented with 2% B27 (a serum free supplement, Invitrogen) containing 50 ng/ml murine NGF 2.5S subunit (Invitrogen). Ganglia were then mechanically dissociated by repeated passing through a fire polished Pasteur pipette. In order to measure HSV axonal transport the neurons were characterized following the extension of axons in SND450 microfluidic devices (Xona Microfluidics) that were mounted on glass coverslips or glass slides [28,43,44]. Glass surfaces were first prepared by overnight incubation in poly-D-lysine (1 ug/ml) in 0.1 M Naborate, pH 8.5. The glass was washed twice in water, dried, and then incubated for 2 h in poly-D-lysine (30 ug/ml), laminin (2 ug/ml) in phosphate buffered saline (PBS). The glass was then washed twice in water and air-dried. SCG neurons were plated in the somal compartments (~ 40,000/device) of microfluidic chambers then after 2 days cytosine arabinoside (araC, 2 μM) was added to the media for 2 days to kill non-neuronal cells. Neurons produced axons extending from the somal chambers into channels connecting to the axonal compartments. Neurons were infected after 6-7 days by adding HSV (8 PFU/cell) into the somal compartments. For experiments measuring HSV spread to non-neuronal cells,
~40,000 HaCaT cells were plated in the axonal compartments of microfluidic devices 24 h before infection and 0.1% human gamma globulin (a source of HSV neutralizing antibodies, Baxter Healthcare) was added to the axonal compartments at the time of virus addition to the somal compartments.

**Antibodies.** Rabbit polyclonal anti-VP26 sera was kindly provided by Prashant Desai (Johns Hopkins University, Baltimore, MD). Mouse monoclonal antibody (MAb) specific for ICP4 (58S) was a gift of Roger Everett (University of Glasgow). Mouse anti-gB MAb (SS10) was kindly provided by Gary Cohen (University of Pennsylvania, Philadelphia, PA). A guinea pig anti-tau was purchased from Synaptic Systems. DyLight fluorescent secondary antibodies were from Jackson Immunoresearch.

**Immunofluorescence microscopy of HSV infected neurons in axonal chamber.** Microfluidic chambers containing SCG neurons and HaCaT cells were disassembled and fixed in 4% paraformaldehyde in PBS for 10 min at 20°C and permeabilized in 0.1% Triton X-100 for 10 min. In some cases, cells were fixed in acetone for 5 min at -20°C then washed extensively with PBS. Cells were incubated with primary antibodies in PBS containing 0.1% Tween20 and 2% normal donkey serum for 1-2 h then cells were washed in PBS containing 0.1% Tween20 and incubated with secondary fluorescent antibodies in PBS containing 0.1% Tween20 and 2% normal donkey serum for 1-2 h. In some cases, nuclei were stained with 600 nM DAPI (4',6-diamidino-2-phenylindole) for 5 min. Microscopy was performed in the Oregon Health and Sciences University Advanced Light Microscopy Core using a Deltavision CoreDV Widefield Deconvolution microscope. Images were captured with a 60X (numerical aperture, 1.42) Plan Apo N objective in three channels: 488, 549, and 649 nm. For quantification of VP26 and gB puncta, ten 10551 μm² images per slide were captured with a minimum of six 0.3 μm z-sections. After deconvolution, the images were processed with ImageJ software by setting VP26 and gB puncta to a minimum intensity threshold of 1500 (at this threshold uninfected cells yield approximately 0 VP26 and gB fluorescence) and a minimum area of at least 7 square pixels (6.4 X 10⁻³ μm²). The puncta quantified by using ImageJ software were also compared to manual
counts of gB and capsid puncta in representative images using softWoRx software (Applied Precision). Counts of capsid and glycoprotein puncta produced using ImageJ software were also corrected for the relative numbers of axons present in different fields, by using tau-specific antibodies to stain axons. HSV infected HaCaT cells expressing the immediate early ICP4 protein were immunostained with an ICP4 MAb and manually counted in 10 axonal compartments involving 3 separate experiments.

**Analyses of HSV replication in SCG neurons.** SCG neurons were plated in 24 well tissue culture dishes (40,000 cells/well) coated with poly-D-lysine and laminin then treated with araC to kill non-neuronal cells for 2 days. Six days after plating, the cells were infected with HSV using 5 PFU/cell. After 2 h, the cells were washed once in Neurobasal media and some cells and media were immediately harvested (2 h timepoint), while other dishes were incubated for 22 or 30 h. Cells were scraped from the dishes into cell culture media, this mixture frozen, sonicated, and HSV titers determined using Vero cells.

**RESULTS**

**HSV mutants with insertion mutations in the gE ET domain.** Previously, we constructed a panel of HSV mutants that express gE molecules with 4 or 5 a.a. insertions within the gE ET domain [20]. Of special interest were mutants F-BAC gE-277 and F-BAC gE-348-4 (here denoted gE-348) that replicated as well as wild type HSV in HaCaT epithelial cells and produced normal amounts of gE, which formed heterodimers with gI, and these gE/gI complexes reached cell surfaces and were incorporated into extracellular virus particles. Mutant F-BAC gE-256 produced a misfolded form of gE that dimerized with gI, but remains stuck in the ER and this mutant was used in some experiments as an additional negative control. F-BAC gE-277 and F-BAC gE-348 were unable to mediate spread between epithelial cells and corneal epithelial cells [20]. Here these mutants were used to test whether HSV gE/gI ET domains are important for axonal transport and spread from neurons to epithelial cells. Before the HSV gE ET domain mutants described above could be used to infect neurons, it was necessary to repair the thymidine kinase (TK) gene in these viruses. F-BAC gE-256, F-
BAC gE-277 and F-BAC gE-348 were constructed using an HSV bacterial artificial chromosome (BAC) copy of HSV DNA in which the BAC was inserted into the TK gene [38]. TK is required for HSV replication in neurons. Viral DNA was co-transfected along with a plasmid containing the HSV TK gene [40] into Vero cells and TK+ viruses selected using HAT media in 143TK- cells, producing TK-repaired mutants denoted: HSV gE-256, gE-277 and gE-348. Replication HSV gE-277 and gE-348 in superior cervical rat (SCG) neurons derived from 18 day old embryos [6,26] was similar to w.t. HSV (Fig.1). Note that these neuronal cultures contain no non-neuronal cells following our modified protocol of cytosine arabinoside treatment [6,28]. Previous studies have shown that HSV gE-null mutants have no defects replication in neurons and exocytosis into neuron culture supernatants [11,20]. We later produced gE-repaired versions of HSV gE-277 and gE-348 (gE-277R and gE-348R), but because there were no defects in replication of HSV gE-277 and gE-348 replication of the repaired viruses was not shown in Fig. 1.

Anterograde axonal transport of HSV capsids and gB into distal axons. To characterize whether the HSV gE ET domain mutants were defective in anterograde axonal transport we used rat SCG neurons that were plated in microfluidic chambers [6,28,43]. These embryonic rat neurons were introduced into the somal compartments of microfluidic devices, so that neuron cell bodies reside in these chambers and extend axons through 450 um microchannels connecting to axonal compartments, where distal axons and axon tips are found. After 6-7 days in culture these neurons were infected with w.t. type HSV, a gE-null mutant, F-gEß [11], gE-277, gE-256, and gE-348, gE-277R and gE-348R by adding virus (8 PFU/neuron) into the somal chambers. After 18 h of infection, distal axons in axonal chambers were simultaneously stained with rabbit VP26-specific (capsid protein) polyclonal antibodies, a gB mouse MAb, and tau-specific (cellular axon protein) antibodies. There were numerous capsid puncta (green) and gB puncta (red) in distal axons (stained with tau antibodies in blue) derived from w.t. type HSV-infected neurons and fewer capsids and gB puncta in axons derived from HSV gE-null infected neurons (Fig. 2, top panels). Both unenveloped (Separate) and enveloped
(Married) capsids were observed as in our previous studies [6,28]. Certain axons were out of the plane of focus or not intensely stained with tau, so that it appeared some puncta might be outside axons, but a closer examination showed that this was not the case, as we previously described [6,28]. Axons derived from neurons infected with HSV mutants gE-277 and gE-348 also displayed few gB puncta and capsids, whereas axons from neurons infected with the gE-repaired viruses contained numerous capsids and gB puncta (Fig. 2, lower panels). We quantified these puncta by capturing 10 images from each of 3 axonal chambers and processing the images with ImageJ software to produce the total numbers of puncta per field. These analyses showed substantially reduced numbers of capsids and gB puncta in distal axons from neurons infected with HSV gE-null, gE-256, gE-277 and gE-348 (Fig. 3). Four other experiments produced similar data (not shown). HSV gE-repaired recombinants, gE-277R and gE-348R, were like w.t. HSV. We concluded that the mutant gE molecules expressed by HSV gE-277 and gE-348 cannot promote efficient axonal transport.

**HSV gE-277 and gE-348 mutants produce mislocalized capsids in neuron cell bodies.** While HSV gE-277 and gE-348 exhibited few capsids and gB in distal axons, it was not clear whether this related to reduced transport within axons or reduced entry of HSV structural components into axons i.e. defects manifest in neuron cell bodies. To characterize this, we imaged proximal axons present within the somal chambers of microfluidic chambers. W.t. HSV-infected neurons exhibited numerous gB puncta (red) and capsids (VP26, green) within proximal axons (Fig. 4A). These puncta were much more difficult to ascribe to individual axons because of the much higher density of axons in somal chambers, compared with axonal chambers. However, it was clear that neurons infected with HSV gE-null, gE-277 and gE-348 displayed markedly fewer capsids and gB puncta, compared with w.t. HSV (Fig. 4 A-D). When the microscope was focused on neuron cell bodies, fluorescence was intense over cell bodies, related to the concentration of capsids and glycoproteins there. In the case of these cell bodies, the tau (blue) fluorescence was subtracted from the images to allow better focus on the cytoplasmic distribution of capsids and gB. In cell bodies of neurons infected with HSV gE-null,
gE-277, and gE-348 there were marked concentrations of capsids that were largely localized at one pole of the neuronal cytoplasm, producing green fluorescence (Fig. 4F, G, H). In these gE-null, gE-277, and gE-348 infected neurons, gB was distributed more uniformly throughout the cytoplasm. By contrast, in w.t. HSV-infected neurons there was more extensive colocalization of capsids with gB and the capsids were much more uniformly distributed over the entire cytoplasm, producing yellow and orange fluorescence (Fig. 4E). There was also some clustering of capsids in clumps (green fluorescence) in the w.t. infected neurons, but more of the capsids were observed randomly dispersed throughout the cytoplasm, compared with that in gE-, 277- and 348-infected neurons (Fig. 4E-H). These studies demonstrated that capsids were extensively mislocalized in cell bodies of neurons infected with HSV gE-null, gE-277, and gE-348.

Neuron-to-epithelial cell spread of HSV gE-277 and gE-348. To characterize the role of the gE ET domain in extracellular spread from neuronal axons to adjacent epithelial cells, we plated HaCaT epithelial cells in the axonal chambers of microfluidic devices that already contained distal axons. HaCaT cells are a keratinocyte cell line [37] and HSV gE mutants display major (8 fold) defects in spread between HaCaT cells [15]. Given that the aim of these studies was to characterize just the spread from infected neuronal axons to epithelial cells and not the spread between epithelial cells, we initially performed a time course experiment to determine when the first HaCaT cells became infected by neuron-derived HSV. Human gamma globulin (h.g.g.), which contains HSV-neutralizing antibodies, was added to the axonal chambers to ensure that virus spread was limited to spread across cell-cell junctions in a form that is resistant to neutralizing antibodies, as pictured in [13]. Neurons were infected in somal compartments with HSV w.t. type HSV or gE-null and HaCaT cells stained with anti-HSV ICP4 antibodies. ICP4 is an HSV immediate early protein found in the nucleus and not in axons. At 18 h we detected primarily (>75%) single HaCaT cells infected with w.t. type HSV (stained with ICP4 antibodies) and in contact with tau antibody-stained axons (Fig. 5). Pairs of infected HaCaT cells were seen in the vast majority of cases involving more than a single infected
HaCaT cell and certain of these cells were clearly the result of spread from axons. After 20 h, there were clumps of infected HaCaT cells frequently involving 8-12 cells, consistent with significant spread beyond a single infected cell. After 22 h, w.t. type HSV had spread to a large groups of HaCaT cells in axonal chambers and by 24 h the majority of cells were infected (Fig. 5). After 16 h, there were very few (<5%) ICP4-expressing HaCaT cells with w.t. type HSV (not shown). Compared with cultures infected with w.t. HSV, there was much less spread of the HSV gE-null mutant to HaCaT cells at 18 h and little spread between HaCaT cells at 20 and 22 h (Fig. 5). Thus, by characterizing spread of HSV mutants from neurons to epithelial cells at 18 h, we could focus on the process of HSV spread from axons to adjacent epithelial cells, rather than spread between epithelial cells.

Neurons were infected in somal chambers with HSV mutants gE-256, gE-277, gE-348 and repaired viruses then ICP4+ HaCaT cells in axonal chambers counted at 18 h. Mutants gE-256 and gE-277 displayed fewer infected HaCaT cells compared with w.t. type HSV infected cultures and with the repaired viruses gE-277R and gE-348R (Fig. 6A, B). Even if one assumes that pairs of infected HaCaT cells represent spread between HaCaT cells and not spread from neurons, the differences between w.t. and gE-277 were still substantial (10 fold). By contrast, HSV gE-348 spread well to infect as many HaCaT cells as w.t. type HSV and the repaired viruses (Fig. 6A, B). These results were surprising, yet were highly reproducible, in 7 experiments HSV gE-348 spread as well as w.t. HSV, while gE-277 did not. Therefore, even under conditions in which HSV gE-348 only transported 5-20% the normal number of capsids and gB puncta into distal axons, HSV gE-348 was able to spread as well as w.t. type HSV from neurons to epithelial cells. Although similar numbers of capsids and gB puncta were observed in axons derived from HSV gE-277-infected neurons, the gE-277/gI mutant protein was unable to mediate axon-to-epithelial cell spread.

**DISCUSSION**

The roles of HSV, PRV and VZV gE/gI molecules in anterograde axonal transport are well established. Loss of either the gE or gI polypeptides disrupts the gE/gI heterodimer and
reduces axonal transport of all viral structural proteins. Our observations with an HSV gE-/US9-
double mutant produced the conclusion that most of the defects in anterograde transport involve
defects in sorting of viral structural components within cell bodies, before entry of viral proteins
into axons [28]. These sorting decisions require TGN-like trafficking motifs in the gE and gI CT
domains that also contribute to virus envelopment and sorting in epithelial cells [14,16,27,45,46].
How the relatively larger gE and gI ET domains contribute to axonal transport has not been
addressed before. Our results here show that HSV mutants gE-277 and 348 cannot function in
anterograde transport better than a gE-null mutant. These small insertion mutations in the gE
ET domain allow gE to fold relatively normally, form heterodimers with gI and become
incorporated into the virion [20].
Models explaining how the gE/gI ET domains function in axonal transport are more
complex compared with representations of how the gE/gI CT domains participate [6,27,28].
Given that the gE/gI and US9 CT domains are present in the cytoplasm, these sequences can
potentially interact with kinesins, kinesin adaptors, or cytoplasmic sorting proteins in neuron cell
bodies or in axons. The Loading hypothesis suggests that the gE/gI and US9 CT domains
participate in sorting of gE/gI, US9, other viral membrane proteins and tegument proteins into
discrete cytoplasmic membrane compartments, e.g. TGN-like membranes, where loading onto
kinesin motors occurs. However, the gE/gI ET domain are present inside cytoplasmic vesicles,
cannot directly interact with cytoplasmic proteins, and must instead interact with luminal or ET
domains of viral or cellular proteins. One possibility is that the gE/gI ET domains interact with
the ET domains of other HSV glycoproteins (gB, gD, gH/gL, gM/gN) leading to their sorting or
assembly into TGN-like membranes promoting loading of essential virion components onto
kinesin motors and entry into axons (see Cartoon, Fig. 7A). By this model, HSV gE-null-null, gE-
277 and gE-348 mutants fail in sorting decisions, so that membrane proteins are loaded less
efficiently onto kinesins (Fig. 7B).
The gE-277 and gE-348 mutations also substantially reduced axonal transport of
capsids. Capsids accumulated in a band at one pole of the neuronal cytoplasm, whereas
capsids produced by w.t. HSV were more uniformly spread throughout the cytoplasm. The effects of the gE ET domain mutations were probably indirect because the gE/gI ET domain cannot interact directly with cytoplasmic capsids or tegument proteins. gE/gI and gD and other glycoproteins interact with certain outer tegument proteins, some that are bound to the surfaces of cytoplasmic membranes and others bound to capsids, and this involves the CT domains of HSV glycoproteins and effects trafficking of tegument proteins [46-50]. Given that outer tegument proteins coat the surfaces of capsids, we anticipate that gE/gI and other HSV glycoproteins might determine the cytoplasmic localization of unenveloped capsids. This fits with evidence that HSV gE/gI and gD possess redundant functions in secondary envelopment, a process involving interactions between glycoproteins and tegument proteins [46,51]. Thus, in this modified Loading hypothesis, the effects of gE ET domain mutations are to cause mislocalization of gE/gI and other HSV membrane and tegument proteins, leading to missorting of tegument-coated unenveloped capsids, so that capsids are inefficiently loaded onto kinesin motors (Fig. 7 A, B).

There was a recent report that PRV gE/gI promotes anterograde transport by facilitating the binding of US9 onto kinesin-3 motors [29]. The authors concluded that PRV US9 is essential for anterograde transport [34], while gE/gI is important but not essential for axonal transport, acting upstream of US9 to promote loading of US9 onto kinesins [29]. By contrast, HSV gE- and US9- mutants each displayed reduced axonal transport of 60-90%, but a double gE-/US9- mutant was completely blocked for transport of capsids and glycoproteins into proximal axons [27,28]. We concluded that HSV gE/gI and US9 act by redundant or overlapping mechanisms, rather than in a linear pathway where one protein acts upstream of the other.

The markedly reduced numbers of capsids and gB puncta in the distal axons of HSV gE-277 and gE-348 infected neurons predicted that there would be diminished spread to adjacent epithelial cells. Surprisingly, there was efficient spread of HSV gE-348, as many HaCaT epithelial cells were infected as with w.t. HSV. We estimated that HSV gE-348 produced ~9000
capsids in an entire axonal chamber and ~100-150 HaCat cells were infected at 18 h. Therefore, even with the reduced numbers of HSV gE-348 capsids and glycoproteins in distal axons, there were numerous infectious HSV particles in these axons, sufficient to spread to 100-150 HaCaT cells. There was no evidence that HSV gE-348 could spread better than wild type HSV, it was more likely that reduced numbers of particles did not compromise spread. By contrast, HSV gE-277 was unable to mediate neuron-to-epithelial cell spread, despite levels of capsids and glycoproteins in distal axons similar to HSV gE-348. We concluded that the gE-277 mutation abolishes the capacity of gE-277/gI to mediate axon-to-epithelial cell spread, whereas gE-348/gI is normal in this process. Axon-to-epithelial cell spread might be considered to include two steps (see Cartoon, Fig. 7C). First, enveloped virions are produced by secondary envelopment at axon tips. The virions are encased in membrane vesicles that must be sorted to axon-epithelial cell junctions and exocytosed. In the second step, extracellular particles adhered onto neuron surfaces can simultaneously interact with epithelial cells at cell-cell junctions then enter the epithelial cells. HSV virions are present at epithelial cell-cell junctions in direct contact with both cells in a compartment that resists neutralizing antibodies [13]. HSV gE-277 fails in one or both of these steps, while gE-348 retains the capacity to mediate this spread.

In summary, we genetically separated two stages in the gE/gI-mediated spread of HSV from neurons to adjacent epithelial cells: i) anterograde axonal transport that was defective for both gE-277 and gE-348 and ii) spread from axons to adjacent epithelial cells that was not mediated by gE-277.

ACKNOWLEDGEMENTS

We are especially indebted to Aurelie Snyder at the Advance Light Microscopy Core at the Jungers Center, OHSU, for her extensive efforts and skill in performing deconvolution microscopy and image analyses. This work was supported by a grant from National Institutes of Health RO1 EY018755 (to D.C.J.).

**FIGURE LEGENDS**

**Figure 1. Replication of HSV gE-277 and gE-348 mutants in rat neurons.** Rat SCG neurons growing in 24 well dishes (~ 40,000 neurons per well) were infected with w.t. type HSV, HSV gE-null, HSV gE-277 or HSV gE-348 using 5 PFU/cell for 2 h then the cells were washed once with media. At this time (2 h) or after 22 or 30 h, the cells were scraped into the culture media, frozen, sonicated then viral titers determined using plaque assays using Vero cells. The experiment was performed in triplicate, the mean titers are shown with standard deviations.
Figure 2. Capsids and gB puncta present in distal axons following infection with HSV gE-277, and gE348. Rat SCG neurons were infected with w.t. (w.t.) HSV, gE-null, HSV gE-277, gE-277-R, gE-348 or gE-348-R using 8 PFU/cell by adding virus in the somal compartments of microfluidic devices then incubated for 18 h. The devices were disassembled and axons in the axonal chambers fixed with paraformaldehyde and simultaneously immunostained with antibodies specific for: VP26 (green, capsids), gB (red), and the microtubule-associated protein tau (blue) then secondary fluorescent antibodies.

Figure 3. Numbers of capsids and gB puncta in distal axons of SCG neurons. A, B. Rat SCG neurons growing in microfluidic devices were infected with w.t. type HSV, HSV gE-256, gE-277, gE-348, gE-277R or gE-348R using 8 PFU/cell by adding virus in the somal chambers. After 18 h the devices were disassembled and axons in the axonal chambers fixed with paraformaldehyde then permeabilized with 0.1% Triton X-100 (panel A) or fixed and permeabilized with acetone (panel B) and simultaneously immunostained with antibodies specific for: VP26, gB, and the microtubule-associated protein tau then secondary fluorescent antibodies. ImageJ software was used to count capsid and gB puncta in 10 distinct 10551 um² fields of the axonal compartments from three separate wells.

Figure 4. Capsids and gB puncta in proximal axons and cell bodies. SCG neurons were infected as described in Fig. 2 for 18 h. Microfluidic devices were disassembled and neuron cell bodies and axons in the somal chambers fixed with paraformaldehyde, permeabilized, and simultaneously immunostained with antibodies specific for: VP26 (capsids, green), gB (red), and the microtubule-associated protein tau (purple-blue) then secondary fluorescent antibodies. In panels A-D images were taken of neuronal axons with efforts made to exclude cell bodies. In panels E-H images were taken of neuronal cell bodies and their associated proximal axons with the tau-specific fluorescence subtracted.

Figure 5. Spread of w.t. type and gE-null HSV from distal axons to adjacent epithelial cells. SCG neurons growing in microfluidic chambers were allowed to produce axons, which extended into the axonal compartment for 6 days then HaCaT cells were plated in the axonal compartment.
Neurons were then infected with w.t. HSV or HSV gE-null (using 804 PFU/cell) by adding virus to the somal compartments. After 2-4 h, 0.1% human gamma globulin (a source of HSV-neutralizing antibodies) was added to the axonal chambers. At the indicated time points the devices were disassembled and cells in the axonal chambers were fixed with 4% paraformaldehyde, permeabilized with 0.1% Triton X-100, and immunostained with antibodies specific for tau (axons, green) and HSV immediate early gene protein ICP4 (HaCaT cells, red), and then secondary fluorescent antibodies and the nuclear dye DAPI (purple-blue).

**Figure 6. Spread of F, gE-, gE-256, gE-277 and gE-348 mutants from distal axons to adjacent non-neuronal cells.** SCG neurons and HaCaT cells were plate in microfluidic chambers and infected with HSV as described in Fig. 5. Cells in the axonal chambers were fixed with 4% paraformaldehyde, permeabilized with 0.1% Triton X-100, and immunostained with ICP4-specific antibodies and the nuclear dye DAPI. **A.** ICP4+ HaCaT cells were manually counted in 10 axonal compartments involving 3 separate wells and the total number of ICP4+ HaCaT cells/axonal compartment is shown with standard deviations. **B.** Another experiment was performed as in panel A, but including repaired HSV gE-277R and gE348R.

**Figure 7. Cartoon depicting models for how gE-277 and gE-348 might fail to promote axonal transport and neuron-to-epithelial cell spread.** **A.** In w.t. HSV-infected neurons, w.t. HSV gE/gI ET domains promote the assembly of other glycoproteins and tegument coated capsids into TGN-like membranes where there is loading of viral structural proteins onto kinesin motors and microtubules. **B.** In neurons infected with HSV gE-null, gE-277, or gE-348, viral glycoproteins and tegument-coated capsids are missorted, so that assembly occurs at intracellular sites distant from where loading onto kinesins occurs. **C.** Unenveloped capsids and vesicles containing glycoproteins arrive at axon tips and secondary envelopment produces enveloped virions. Virions inside membrane vesicles must be sorted to the surfaces of axon tips where exocytosis occurs. Extracellular virions that remain bound on axon surfaces (at axon-epithelial cell junctions) interact with epithelial cells, promoting rapid entry into epithelial cells.
