Received 15 October 2001/Accepted 10 January 2002

The frequency of cytomegalovirus (CMV)-specific CD4+ T lymphocytes was determined in CMV-seropositive rhesus macaques with or without simian immunodeficiency virus (SIV) infection by using the sensitive assays of intracellular cytokine staining and gamma interferon ELISPOT. Both techniques yielded 3- to 1,000-fold-higher frequencies of CMV-specific CD4+ T lymphocytes than traditional proliferative limiting dilution assays. The median frequency of CMV-specific CD4+ T lymphocytes in 23 CMV-seropositive SIV-negative macaques was 0.63% (range, 0.16 to 5.8%). The majority of CMV-specific CD4+ T lymphocytes were CD95+ and CD27lo but expressed variable levels of CD45RA. A significant reduction (P < 0.05) in the frequency of CMV-specific CD4+ T lymphocytes was observed in pathogenic SIV-infected macaques but not in macaques infected with live attenuated strains of SIV. CMV-specific CD4+ T lymphocytes were not detected in six of nine pathogenic SIV-infected rhesus macaques. CMV DNA was detected in the plasma of four of six of these macaques but in no animal with detectable CMV-specific CD4+ T lymphocytes. In pathogenic SIV-infected macaques, loss of CMV-specific CD4+ T lymphocytes was not predicted by the severity of CD4+ T lymphocytopenia. Neither was it predicted by the pre-SIV infection frequencies of CD45RA+ or CCR5+ CMV-specific CD4+ T lymphocytes. However, the magnitude of activation, as evidenced by the intensity of CD40L expression on CMV-specific CD4+ T lymphocytes pre-SIV infection, was three- to sevenfold greater in the two macaques that subsequently lost these cells after SIV infection than in the two macaques that retained CMV-specific CD4+ T lymphocytes post-SIV infection. Future longitudinal studies with these techniques will facilitate the study of CMV pathogenesis in AIDS.

Although the widespread use of highly active antiretroviral therapy has resulted in a significant decline in the incidence of all opportunistic infections in AIDS, cytomegalovirus (CMV) continues to be an important pathogen in immunosuppressed human immunodeficiency virus (HIV)-infected individuals (29). There are many similarities in the natural history and course of simian and human CMV infection. CMV infection is widely prevalent in captive rhesus macaques; maternal antibodies to CMV wane around 1 year of age, and seroconversion following natural infection occurs soon thereafter (15, 39). Moreover, CMV infection is asymptomatic in immunocompetent rhesus macaques (32), and CMV disease has only been reported in immunosuppressed animals (3).

Since activated CD4+ T lymphocytes are specifically targeted and depleted during the course of HIV or SIV infection (10, 38), loss of CMV-specific CD4+ T lymphocytes is likely to be an important mechanism underlying the occurrence of CMV disease in AIDS. The requirement of CD4+ T lymphocytes for effective viral clearance has been elegantly demonstrated in the murine animal model for a wide variety of pathogens, and several mechanisms have been described. One important mechanism is the help provided by CD4+ T lymphocytes for the generation or maintenance of CTL. Primary CTL responses to herpes simplex virus and influenza A virus are not generated in the absence of CD4+ T lymphocytes (12, 33). In chronic lymphocytic choriomeningitis virus infection, although primary CTL responses are unaffected in the absence of CD4+ T lymphocytes, memory CTL responses gradually decline and lead to recrudescence of viremia (4, 22, 40). In this model, the loss of memory CTL responses results both from deletion of CTL, as well as from surviving memory CTL being rendered functionally unresponsive (44). A direct antiviral effector function of CD4+ T lymphocytes has also been described (6, 21). In murine gammaherpesvirus infection, loss of
control of virus replication in CD4-deficient mice is not associated with decline in the number or functionality of murine gammaherpesvirus-specific CTL (30). Instead, the antiviral effect appears to be mediated by a B-cell-independent, direct effector function of CD4+ T lymphocytes which is dependent on gamma interferon (IFN-γ) production (6). Finally, CD4+ T lymphocytes appear to be required for the production of virus-specific neutralizing antibodies, as in the instance of vesicular stomatitis virus infection (21). In humans, evidence for a protective role of CD4+ T lymphocytes comes from studies in CMV and HIV infection. In bone marrow transplant recipients, maintenance of adoptively transferred CMV CTL is dependent on the presence of an intact CMV-specific CD4+ T lymphocyte response (42). Strong CD4 T helper responses to p55gag antigen are detected in HIV-infected long-term non-progressors and are associated with control of HIV viremia (27).

The development of sensitive techniques such as enzyme-linked immunospot (ELISPOT) and flow cytometric detection of intracellular cytokines (ICC) to delineate antigen-specific cells at the single cell level has provided new insights into pathogen-specific immune responses (23). In the present study, we adapted these techniques to determine the nature of the CMV-specific CD4+ T lymphocyte response in rhesus macaques with or without SIV infection. Our results show that the ELISPOT and ICC assays are 3- to 1,000-fold more sensitive than the traditional proliferative limiting dilution assay (LDA) for measurement of CMV-specific CD4+ T lymphocytes. Rhesus macaques infected with pathogenic SIV for a median duration of 4.5 months had significantly decreased frequencies of CMV-specific CD4+ T lymphocytes in their peripheral blood. In these animals, loss of CMV-specific CD4+ T lymphocytes was not predicted by the extent of CD4+ T lymphocyteopenia. Instead, it was associated with increased CMV and SIV viral loads. Pre-SIV infection frequencies of CD45RA+CCR5+ CMV-specific CD4+ T lymphocytes did not predict their depletion subsequent to SIV infection. However, the extent of activation after in vitro antigen-specific stimulation, as manifested by the intensity of CD40L expression on CMV-specific CD4+ T lymphocytes, was greater in macaques that subsequently lost these cells after SIV infection.

**MATERIALS AND METHODS**

**Animals.** Rhesus macaques with and without SIV infection were included in the study. Animals were housed in the specific pathogen free or conventional colony of the New England Regional Primate Research Center in accordance with federal and institutional guidelines for animal care (1). Rhesus macaques were screened for naturally acquired CMV infection by testing sera for antibodies to rhesus CMV. In SIV-infected rhesus macaques with undetectable antibodies to CMV, sera archived prior to SIV infection were tested in order to distinguish CMV-seronegative animals from CMV-seropositive animals that had lost CMV antibodies after SIV infection. Among SIV-infected macaques, only CMV-seropositive animals were included in the study.

**CMV ELISA.** Serum from rhesus macaques was screened for antibodies reacting to rhesus CMV by enzyme-linked immunosassay (ELISA). Rhesus CMV antigen coating the ELISA plates was prepared from a previously described clinical isolate of rhesus CMV (15). CMV-infected primary monkey fibroblast cells that had progressed to complete cytopathic effect were harvested and subjected to low-speed centrifugation at 1,500 rpm for 10 min to eliminate cell debris. The supernatant was filtered through a 0.45-μm-pore-size filter and subjected to ultracentrifugation at 17,000 rpm for 3 h at 4°C. The virus pellet was resuspended in buffer TNE (20 mM Tris, pH 7.5; 100 mM NaCl; 1 mM EDTA) and purified by chromatography on a 10-ml column of Sepharose 4B (CL-4B-200, Sigma, St. Louis, Mo.) at room temperature with buffer TNE as the column buffer. The cultured virus was collected in microcentrifuge tubes and spun cold in a microcentrifuge at 13,000 rpm for 1 h. The virus pellet was resuspended in 150 μl of 0.5% Triton X-100 in phosphate-buffered saline (PBS), and the protein concentration was determined on a spectrophotometer. The optimal concentration of antigen for coating the ELISA plate was determined by titration with a positive control serum.

Test serum was added to antigen coated wells and incubated for 1 h at room temperature. Wells were washed with PBS containing 0.05% Tween 20 and subsequently incubated with alkaline phosphatase-labeled antibody to the Fc fragment of human immunoglobulin G (IgG; Kirkegaard & Perry Laboratories, Inc., Gaithersburg, Md.) for 1 h at room temperature. After being washed, the wells were incubated with substrate solution (p-nitrophenylphosphate in diethanolamine) in the dark for 30 min at room temperature. The reaction was stopped by addition of 5% EDTA, and the absorbance at 410 nm was determined on an ELISA reader.

**Antibodies.** Monoclonal antibodies (MAb) used for cosstimulation in the ICC assays included antihuman CD28 MAb (clone 28.2; BD Pharmingen, San Diego, Calif.) and antihuman CD49d MAb (clone 9F10; Pharmingen), each at a final concentration of 10 μg/ml. Affinity-purified antibody F(ab')2 fragments of goat anti-mouse IgG(H+L) (Kirkegaard & Perry) were used for cross-linking the costimulatory antibodies. Fluorochrome-conjugated antihuman MAbs were obtained from BD Pharmingen unless otherwise indicated. These included CD4 allophycocyanin (APC), CD69 phycoerythrin (PE) or APC, CD27 PE, CD45RA peridinin chlorophyll protein (PerCP; custom conjugated at Chromosome, Inc., Mountain View, Calif.), CD95 PE (Caltag Labs, Burlingame, Calif.), CD154 PE (clone TRAP1), CCR5 PE (clone 3A9), tumor necrosis factor alpha (TNF-α), fluoresein isothiocyanate (FITC), or PE (clone MAb11), and IFN-γ FITC or PE (clone B27 or clone 48BB).

**Stimulation of CD4+ T lymphocytes.** Rhesus CMV antigen for stimulation of CD4+ T lymphocytes was prepared from primary monkey fibroblast lines infected with a clinical isolate of rhesus CMV (15). After infection had progressed to >90% cytopathic effect, the cells were subjected to multiple freeze-thaw cycles in order to release cell-associated virus, followed by sonication and centrifugation at 2,000 rpm for 15 min. The virus-containing supernatant was heat-inactivated at 56°C for 30 min, and the protein concentration was determined on a spectrophotometer (GeneQuant II; Pharmacia Biotech, Cambridge, United Kingdom). Control antigen prepared from uninfected primary monkey fibroblast lines was used at the same protein concentration as the CMV antigen. For superantigen stimulation, staphylococcal enterotoxin A (SEA) and staphylococcal enterotoxin B (SEB) were used together, each at a final concentration of 100 ng/ml (Sigma).

**ICC staining assay.** Our assay represents a modification of the technique developed by Waldrop et al. to measure CMV-specific CD4+ T lymphocytes in human subjects (41). Peripheral blood mononuclear cells (PBMC) were stimulated with antigen (CMV or superantigen) in the presence of the costimulatory antibodies. Fluorochrome-conjugated antihuman MAbs were obtained from BD Pharmingen unless otherwise indicated. These included CD4 costimulatory antibodies. Fluorochrome-conjugated antihuman MAbs were obtained from BD Pharmingen. Anti-mouse IgG(H+L) (Kirkegaard & Perry Laboratories, Inc.) were used for cross-linking the conjugated antibody F(ab')2 fragments of goat anti-mouse (GAM) IgG for optimal cosstimulation. Polyethylene tubes (12 by 75 mm) precoated with 2.5 μg of GAM IgG/ml in 50 mM TrisCl (pH 8.6), followed by incubation with 10 μg each of anti-CD28 and anti-CD49d/IL-2, were used for stimulation. PBMC were stimulated with antigen for 6 h and Brefeldin A (Sigma) at 10 μg/ml was added for the final 4 h of stimulation. At the end of stimulation, cells were surface stained with conjugated anti-CD4 MAb for 30 min at 4°C. In some experiments, cells were also surface stained with conjugated MAbs to CD45RA, CD27, CD45, or CCR5. Cells were subsequently fixed and permeabilized with successive incubations in FACS Lysing Solution (Becton Dickinson Immunochemistry Systems [BDIS]) and FACS Permeabilizing Solution (BDIS). Permeabilized cells were incubated with conjugated anti-CD69 or anti-CD154 (CD40L) and with anti-cytokine MAbs for 30 min at 4°C, washed, and kept overnight at 4°C in 2% paraformaldehyde. Two hundred thousand events were collected on a FACSCalibur (BDIS), and the data were analyzed by CELLQuest. Antigen-specific cells were defined as CD4+ T lymphocytes that coexpressed CD69 and the cytokine of interest after antigen-specific stimulation.

**IFN-γ ELISPOT assay.** PBMC suspended in RPMI containing 10% FBS (R-10 medium) were placed in 96-well microtiter plates coated with anti-mouse IFN-γ MAb MD-1 (U-Cytech, Utrecht, The Netherlands) (34). PBMC were plated in duplicate at twofold dilutions ranging from 5 × 104 cells/well to 0.3 × 104 cells/well. Cells were stimulated overnight with phorbol myristate acetate (PMA) and control antigen at 37°C in a 5% CO2 incubator. After 16 to 24 h, cells were removed by extensive washing and the wells were serially incubated with a biotinylated anti-mouse IFN-γ detector antibody (U-Cytech) followed by gold-labeled anti-biotin IgG (U-Cytech); finally, an activator mix (U-Cytech) was

RESULTS

Determination of optimal conditions for detection of CMV-specific CD4+ T lymphocytes in rhesus macaques by the flow cytometric ICC assay. A variety of variables were tested to determine the optimal experimental conditions necessary for flow cytometric detection of antigen-specific CD4 cells in rhesus macaques. The optimal conditions for inducing production of TNF-α in PBMC of rhesus macaques were initially determined by stimulation with the superantigens SEA and SEB in the absence or presence of antihuman mAbs to the costimulatory molecules CD28, CD49d, and CD5.

Cross-linked, but not soluble, costimulatory anti-CD28 mAb resulted in a roughly twofold enhancement of the frequency of TNF-α-secreting cells after superantigen stimulation (Fig. 1a). The use of two costimulatory antibodies, anti-CD28 in combination with anti-CD49d or anti-CD5, resulted in an additional three- to fourfold enhancement of the specific cytokine signal and did not result in increased background in the absence of specific stimulation (Fig. 1b and data not shown). The costimulatory antibodies enhanced antigen-specific cytokine secretion in a dose-dependent manner, and the optimal concentrations of CD28 and CD49d mAbs were each determined to be 10 μg/ml (data not shown). In all subsequent experiments, unless otherwise stated, cross-linked anti-CD28 and anti-CD49d mAbs were used together at 10 μg/ml each for costimulation.

Other experimental conditions that were found to be essential for obtaining low-noise and highly specific cytokine signals included the use of freshly isolated PBMC that were either used the same day or cryopreserved immediately for later use, antigen-specific stimulation conducted in tubes slanted 5° above horizontal as described by Waldrop et al. (41), the use of FITC-conjugated anti-cytokine mAb along with PE-conjugated CD69 mAb, and the optimal concentration of CMV antigen. CMV-specific cytokine signals were reduced >90% in PBMC when kept overnight prior to stimulation or when there was an overnight delay prior to separation of PBMC from whole blood (data not shown). In cryopreserved PBMC, the frequency of CMV-specific CD4+ T lymphocytes was roughly 70% of that observed in freshly isolated and stimulated PBMC (data not shown). For the purpose of this analysis, all frequencies of CMV-specific CD4+ T lymphocytes were determined on PBMC that had been isolated and cryopreserved on the day of blood collection.

Quantitation of CMV-specific CD4+ T lymphocytes by ICC. Using optimal conditions for ICC assays as described above, we were able to detect recently activated (CD69+) CD4+ T lymphocytes secreting IFN-γ or TNF-α in CMV-seropositive rhesus macaques after stimulation with whole-virus rhesus CMV antigen (Fig. 2a). Cytokine-secreting CD4+ T lymphocytes were not detected after stimulation with control antigen in CMV-seropositive macaques, nor were they detected after CMV stimulation in CMV-seronegative macaques (Fig. 2a). The cytokine response of CD4+ T lymphocytes was major histocompatibility complex (MHC) class II restricted, since it was decreased >80% when PBMC were incubated with 50 μg of antibodies to MHC class II DR, DP, or DQ (BD Pharmingen)/ml for 30 min at 37°C prior to CMV stimulation (data not shown). Both IFN-γ and TNF-α were detected after CMV-specific stimulation. Although the frequency of TNF-α-secret-
ing CMV-specific CD4+ T lymphocytes exceeded the frequency of CMV-specific IFN-γ-secreting CD4+ T lymphocytes in most animals, the production of both cytokines was highly correlated, with an R^2 value of 0.85 (Fig. 2b). In separate experiments, we demonstrated that >90% of the CMV-specific IFN-γ-secreting CD4+ T lymphocytes also secreted TNF-α (Fig. 2c).

Using this technique, we determined the frequency of CMV-specific CD4+ T lymphocytes in 46 rhesus macaques (Table 1). In 23 CMV-seropositive SIV-naive rhesus macaques with a median age of 12 years (range, 2.7 to 22 years), the frequency of CMV-specific CD4+ T lymphocytes ranged between 0.16% and 5.8% (median, 0.63%) and varied less than twofold over a 6-month period (data not shown). The ICC assay was highly sensitive and specific, since in eight CMV-seronegative rhesus macaques, <0.04% CD69+ IFN-γ-secreting CD4+ T lymphocytes were detected after CMV-specific stimulation (range, 0.0 to 0.04%; median frequency, 0.01%). The lower limit of CMV-specific detection determined as three SDs above the mean frequency of CD69+ IFN-γ+ CD4+ T lymphocytes in the CMV-seronegative macaques was 0.08%. The ICC assay was also highly reproducible for enumerating CMV-specific CD4+ T lymphocytes in rhesus macaques. In CMV-seropositive rhesus macaques, the assay had a low intraassay and interassay variation. The intraassay coefficient of variation for replicates of the same sample assayed at two different timepoints 3 to 6 months apart ranged between 0.10 and 0.51 (mean ± SD, 0.29 ± 0.14).

Comparison of ICC assay, ELISPOT assay, and proliferative LDA for enumeration of CMV-specific CD4+ T lymphocytes in rhesus macaques. The frequency of CMV-specific CD4+ T lymphocytes determined by IFN-γ ICC assay, IFN-γ ELISPOT assay, and proliferative LDA was compared in 10 CMV-seropositive rhesus macaques (Fig. 3a). The frequency of CMV-specific CD4+ T cells detected by ICC assay was 1 to 3 logs greater than that determined by proliferative LDA (P = 0.0002; Mann-Whitney U test), while frequencies determined by IFN-γ ELISPOT assay were 3- to 100-fold greater than those obtained by proliferative LDA (P = 0.0002; Mann-Whitney U test). The frequency of CMV-specific CD4+ T lymphocytes determined by IFN-γ ICC assay was 1.3- to 16.3-fold higher than that determined by IFN-γ ELISPOT assay (P = 0.005; Mann-Whitney U test).

As expected, we observed a significant positive correlation between the frequency of CMV-specific CD4+ T lymphocytes determined by IFN-γ ICC and IFN-γ ELISPOT assays (Fig. 3b). However, there was no correlation between the frequency of CMV-specific CD4+ T lymphocytes determined by the ICC assay and proliferative LDA (Fig. 3b). Neither did we observe a correlation between IFN-γ ELISPOT assay and proliferative LDA (Fig. 3b). The lack of relationship between the assays with different readouts, i.e., the proliferation after long-term stimulation as opposed to cytokine-secretion after short-term stimulation, appeared to be age related (Fig. 3c).
4 of 4 juvenile macaques of <3 years of age, CMV-specific CD4⁺ T lymphocytes were not detected by proliferative LDA, although they were detected at levels comparable to adult macaques when measured by ELISPOT or ICC assays (Fig. 3c). We observed a significant positive correlation between the age of an animal and the frequency of CMV-specific CD4⁺ T lymphocytes determined by proliferative LDA ($R^2=0.43$; $P$ value, 0.03; data not shown), but not by IFN-γ ELISPOT or IFN-γ ICC assays (data not shown).

**Heterogeneity in phenotype of CMV-specific CD4⁺ T lymphocytes among SIV-naive CMV-seropositive rhesus macaques.** Since antigen-specific cells are visualized by the ICC assay, we used it to characterize the phenotype of CMV-specific CD4⁺ T lymphocytes in nine SIV-naive CMV-seropositive...
rhesus macaques (Table 2). CMV-specific CD4+ T lymphocytes were examined with regard to the surface expression of CD45RA, CD27, and CD95, markers commonly employed to characterize memory cells (8, 9). The expression of CD45RA, CD27, and CD95 on CMV-specific CD4+ T lymphocytes varied considerably among animals, and two polar patterns were observed (Fig. 4 and Table 2). One pattern demonstrated by animals MM 214.87 and MM 147.86 (Fig. 4) consisted of CMV-specific CD4+ T lymphocytes being predominantly CD45RA+ or CD45RA−. The other pattern demonstrated by MM 192.88 and MM 150.85 consisted of CMV-specific CD4+ T lymphocytes being predominantly CD45RA+ or CD45RA− (Fig. 4). The differential expression of CD45RA on CMV-specific CD4+ T lymphocytes did not appear to be related to differences in the time of acquisition of natural CMV infection, since all of the examined animals were >8 years of age and group housed and thus likely to have seroconverted by the age of 1 year. In contrast to the expression of CD45RA, the expression of CD27 and CD95 on CMV-specific CD4+ T lymphocytes was homogeneous in all of the animals (Table 2 and Fig. 4). In two of two animals, the expression of CD45RA, CD27, and CD95 on CMV-specific CD4+ T lymphocytes was stable over a 3- to 6-month period.

Cross-sectional analysis of the frequency of CMV-specific CD4+ T lymphocytes in normal and SIV-infected rhesus macaques. Depletion of CD4+ T lymphocytes is a hallmark of pathogenic lentiviral infection, and loss of pathogen-specific CD4+ T lymphocytes is likely to be an important mechanistic feature of the degree of CD4+ T lymphocyte depletion in the nine pathogenic SIV-infected rhesus macaques (Fig. 6a). Notably, one SIVmac251-infected rhesus macaque with profound and sustained CD4+ T lymphocyte depletion was detected in 23 of 23 CMV-seropositive SIV-naive macaques and in 6 of 6 macaques infected with live attenuated strains of SIV, they were detected in only 3 of 9 macaques infected with pathogenic SIV (Fig. 5). The difference in frequency of CMV-specific CD4+ T lymphocytes between normal and pathogenic SIV-infected rhesus macaques was unlikely to be age-related since we did not observe a relationship between age and frequency of CMV-specific IFN-γ-secreting CD4+ T lymphocytes in normal CMV-seropositive rhesus macaques.

Predictors of loss of CMV-specific CD4+ T lymphocytes in pathogenic SIV-infected rhesus macaques. In HIV-infected humans, CMV disease is a late manifestation of AIDS and generally occurs when the peripheral CD4 count drops below 50/μl (28). We investigated whether CD4+ T lymphocytopenia, high SIV viral loads, or CMV viremia were factors associated with the depletion of CMV-specific CD4+ T lymphocytes in pathogenic SIV-infected macaques. At the time of the cross-sectional analysis, SIV-infected macaques with undetectable CMV-specific CD4 cells had been infected for a median duration of 4.5 months (range, 3.5 to 26 months), while the median duration of SIV infection in the three macaques with detectable CMV-specific CD4 cells was 26 months (range, 3.5 to 26 months). We did not observe any relationship between the degree of CD4+ T lymphocytopenia and loss of CMV-specific CD4+ T lymphocytes in the nine pathogenic SIV-infected rhesus macaques (Fig. 6a). Notably, one SIVmac251-infected rhesus macaque with profound and sustained CD4+ T lymphocytopenia for >1 year never lost its CMV-specific CD4+ cells. At the time that this animal finally succumbed to AIDS (45 days since the time point used in the cross-sectional analysis), 2.1% of its CD4+ T lymphocytes were still CMV specific (data not shown). Since macaques infected with live attenuated strains of SIV had undetectable SIV viremia and normal frequencies of CMV-specific CD4+ T lymphocytes, we investigated whether lower SIV viral loads in pathogenic SIV-infected macaques correlated with the persistence of CMV-specific CD4+ T lymphocytes. SIV-infected macaques with lower levels of SIV RNA in plasma (<10^6 copies/ml) had a higher mean frequency of CMV-specific CD4+ T lymphocytes compared to macaques with a level of SIV RNA in plasma of >10^6 copies/ml (Fig. 6b), although this difference did not reach statistical significance (P = 0.12; Mann-Whitney U test). Similarly, an inverse correlation observed between plasma SIV RNA and frequency of CMV-specific CD4+ T lymphocytes was not statistically significant (ρ = -0.37; P = 0.30). Finally, levels of SIV RNA plasma were higher in four pathogenic SIV-infected macaques with
detectable CMV DNA in plasma (median, 1.3 \times 10^8; range, 3.1 \times 10^8 to 8 \times 10^8) compared to 5 macaques with undetectable levels of CMV DNA in plasma (median, 5 \times 10^7; range, 4.6 \times 10^7 to 2.1 \times 10^7), although this difference also failed to reach statistical significance (P = 0.09; Mann-Whitney U test).

Finally, we investigated the relationship between loss of CMV-specific CD4^+ T lymphocytes and the CMV viral load. CMV DNA in plasma was detected by real-time PCR in four of six pathogenic SIV-infected rhesus macaques with undetectable CMV-specific CD4^+ T lymphocytes in their peripheral blood.

\[ ^a \text{NT, not tested.} \]
blood (Fig. 6c). It was not detected in three of three pathogenic SIV-infected macaques with detectable CMV-specific CD4\(^+\) T lymphocytes (Fig. 6c). Nor was it detected in any of the SIV-naive rhesus macaques or in macaques inoculated with live attenuated strains of SIV (data not shown). Pathogenic SIV-infected macaques with undetectable CMV DNA in plasma had significantly higher frequencies of CMV-specific CD4\(^+\) T lymphocytes than animals with detectable CMV DNA in plasma (\(P = 0.03\); Mann-Whitney U test; Fig. 6c). Three of four animals with detectable CMV DNA in plasma had evidence of CMV disease by the time they died of AIDS (Table 3). Two macaques with >1,000 copies of CMV DNA/ml of plasma died within a week of analysis and had histological evidence of CMV pneumonitis (Table 3). Two macaques with <1,000 copies of CMV DNA/ml of plasma died >9 months later, and one had evidence of CMV arteritis at necropsy (Table 3).

**Phenotype of CMV-specific CD4\(^+\) T lymphocytes pre-SIV infection as a predictor of subsequent loss post-SIV infection.** Since SIV and HIV can selectively deplete different memory populations of CD\(^+\) T lymphocytes (35, 37, 43), we examined whether differences in the phenotype of CMV-specific cells, including the expression of CD45RA, CCR5, and activation markers, could account for differential susceptibility to the loss of CMV-specific CD4\(^+\) T lymphocytes after SIV infection. In six of nine pathogenic SIV-infected macaques, PBMC archived prior to SIV infection were available to be examined by the ICC assay. Of these, two animals had detectable CMV-specific CD4\(^+\) T lymphocytes and four had lost their CMV-specific CD4\(^+\) T lymphocytes after SIV infection (Table 4). Similar to SIV-naive animals, a heterogeneous pattern of CD45RA expression was observed on the surface of CMV-specific CD4\(^+\) T lymphocytes, which was indistinguishable between the two animal groups (Table 4). Up to 18% of CMV-specific CD4\(^+\) T lymphocytes in the peripheral blood expressed CCR5 on their surface (Table 4). Macaques that had lost their CMV-specific CD4\(^+\) T lymphocytes after SIV infection did not have a higher frequency of CCR5 positive CMV-specific CD4\(^+\) cells in peripheral blood (Table 4). Since SIV and HIV preferentially replicate in activated cells, we also examined whether the degree of activation of CMV-specific CD4\(^+\) T lymphocytes after in vitro CMV stimulation differed between animals. CMV-specific CD4\(^+\) T lymphocytes from all six macaques had lower levels of surface CD4 expression than the total population of

**FIG. 4.** Expression of CD45RA, CD95, and CD27 on the surface of CMV-specific CD4\(^+\) T lymphocytes. Representative data from four SIV negative, CMV-seropositive adult rhesus macaques are shown. The dot plots shown are gated on CD4\(^+\) T lymphocytes.

---
CD4⁺ T lymphocytes (Fig. 7a). We did not observe a significant difference in the degree of CD69 upregulation on CMV-specific CD4⁺ T lymphocytes between animals that retained or lost their CMV-specific CD4⁺ cells after SIV infection (Fig. 7b). In four animals, we also examined whether there were differences in the pattern of CD154 (CD40L) expression on CMV-specific CD4⁺ T lymphocytes. After CMV stimulation, CD154 (CD40L) was upregulated in 73 to 90% of the CMV-specific IFN-γ-secreting CD4⁺ T lymphocyte population (Table 4). Interestingly, the peak fluorescent intensity of CD154 (CD40L) on CMV-specific CD4⁺ cells from two animals that had lost their CMV-specific CD4⁺ T lymphocytes was three- to sevenfold higher than that observed in two animals that did not lose their CMV-specific CD4⁺ T lymphocytes (Fig. 7c). Although the small number of animals precludes a definitive conclusion, this observation suggests the possibility that preexisting differences in the degree of activation of antigen-specific CD4 cells between animals may be a factor contributing to susceptibility to destruction after SIV infection.

**DISCUSSION**

In this study we characterized CMV-specific CD4⁺ T-lymphocyte responses in the peripheral blood of rhesus macaques with or without SIV infection by using techniques that detect cytokine-secreting antigen-specific T lymphocytes at the single-cell level. In SIV-uninfected, naturally CMV-infected rhesus macaques, 0.16 to 5.8% of the circulating pool of CD4⁺ T lymphocytes were CMV specific. Similar or higher frequencies were observed in macaques that had been infected for >8 years with live attenuated strains of SIV. In contrast, the majority of animals infected with pathogenic SIV had no detectable peripheral CMV-specific CD4⁺ T lymphocytes. In these animals, loss of CMV-specific CD4⁺ T lymphocytes was associated with an increase in CMV viral load, suggesting that CD4⁺ T lymphocytes contribute to in vivo control of CMV replication.

The absence of CMV-specific CD4⁺ T lymphocytes in the majority of pathogenic SIV-infected macaques is in contrast to observations in HIV-infected human subjects. By the ICC assay, CMV-specific CD4⁺ T lymphocytes are detected at normal to higher frequencies in HIV-infected individuals, despite the presence of significant CD4⁺ T lymphocytopenia or high HIV viral loads (24, 41). In our study, although the frequency of CMV-specific CD4⁺ T lymphocytes in healthy, SIV-naïve CMV-seropositive rhesus macaques was comparable to that reported in human subjects, CMV-specific CD4⁺ cells were absent in the majority of pathogenic SIV-infected macaques. The discrepancy between the results in human subjects and the simian model may be a species-specific difference or may be due to differences in the stage of disease or to differences in the biology of HIV and SIV infection. Unlike the relatively prolonged course of asymptomatic HIV infection, SIV typically produces AIDS in macaques within 1 year of infection. Although it is possible that the animals were surveyed late in the
course of infection at a time when they had already developed AIDS, it is unlikely to account for the discrepancy since, in HIV-infected individuals, there was no correlation between the frequency of CMV-specific CD4+ T lymphocytes and the stage of HIV disease (41). Further, differences in duration of SIV infection or the severity of CD4+ T lymphocytopenia did not differentiate macaques that lost their CMV-specific CD4+ T lymphocytes from those that continued to have detectable CMV-specific CD4+ cells after SIV infection. Recently, there have been reports of decreased CMV-specific CD4+ T lymphocytes in HIV-infected individuals with active CMV end-organ disease (11, 18). In our study, increased CMV viral load in plasma (b), and levels of CMV DNA in plasma (c) in CMV-seropositive rhesus macaques with pathogenic SIV infection. Although the decline in HIV viremia after institution of HAART (highly active antiretroviral therapy) is generally associated with significant gains in pathogen-specific immune responses, persistent deficits in CMV-specific CD4+ T lymphocytes despite adequate control of HIV viremia have been described, suggesting a selective destruction of CMV-specific cells (17). In our study, although two-thirds of the pathogenic SIV-infected rhesus macaques had lost their CMV-specific CD4+ T lymphocytes pre-SIV infection, and there was no difference in the frequency of CD45RA+ or CD45RA- CMV-specific CD4+ T lymphocytes between macaques that lost or did not lose these cells after SIV infection. Similarly, CCR5 was expressed in <20% of CMV-specific CD4 cells pre-SIV infection, and there were no differences between the SIV-infected animals to account for the preservation of CMV-specific CD4+ cells in selected animals. Since a higher frequency of CCR5-positive CD4+ T lymphocytes is detected among gut-associated lymphocytes, the first cells to be targeted by SIV (36, 37), it is possible that macaques that lost their CMV-specific CD4+ T lymphocytes had higher frequencies of CCR5 positive CMV-specific CD4+ cells in their guts. Interestingly, albeit in a very small number of animals, we observed a difference in CD40L

expression between animals. Pre-SIV, the intensity of CD40L expression on CMV-specific CD4+ T lymphocytes was three- to sevenfold higher in two macaques that lost their CMV-specific CD4+ cells, in contrast to two animals that continued to have detectable CMV-specific CD4+ cells. The small number of animals precludes any definite conclusions but suggests that variation in the degree of activation of antigen-specific CD4+ cells between animals may be a factor contributing to differential susceptibility to SIV infection. Prospective studies on larger numbers of animals will be required to determine whether upregulation of CCR5 and other memory or activation markers on CMV-specific CD4+ T lymphocytes selectively predisposes animals to destruction of their CMV-specific CD4+ cells after SIV infection.

In the present study, we successfully adapted the ICC and ELISPOT assays to detect CMV-specific CD4+ T lymphocytes in rhesus macaques. Although the ICC assay can detect frequencies of antigen-specific cells that are 1 to 2 logs higher than those reported in the earlier literature by LDA, there are few published studies showing a head-to-head comparison of all three assays (16). As expected, comparison with traditional proliferative assays showed the cytokine assays to be more sensitive. However, to our surprise, although a strong positive correlation was observed between the ELISPOT and ICC assays, we did not observe a correlation between the ICC assay and the proliferative LDA. The lack of correlation appeared to be age dependent. Juvenile rhesus macaques had high frequencies of CMV-specific CD4+ cells detected by the cytokine assays, although the proliferative LDAs scored negative. The discrepancy between the proliferative and cytokine assays may reflect the differences inherent in the assay system, in that a positive readout in the proliferative LDA is dependent not only on the initial frequency of antigen-specific cells but also on their ability to expand exponentially over a 5- to 6-day stimulation period (23). Another possibility is that CMV-specific CD4+ T lymphocytes are heterogeneous with respect to their proliferative and cytokine-secreting abilities. In primary CMV infection in renal transplant recipients, CMV-specific CD4 cells were predominantly CD45RA+/CCR5- and Ki-67+, a phenotype remarkably different from quiescent infection (25). It is likely that these phenotypic differences are associated with different functional abilities of memory CD4 cells. Thus, juvenile rhesus macaques may have a higher proportion of activated CMV-specific CD4+ cells which score poorly in traditional proliferative assays either due to apoptosis in long-term stimulation cultures or due to a decreased proliferative ability. A dichotomy between cytokine-secreting and proliferative CD4+ T lymphocytes is likely to be a factor contributing to differential susceptibility to SIV infection.

![FIG. 7. Level of expression of CD4, CD69, and CD154 (CD40L) on CMV-specific CD4+ T lymphocytes in six rhesus macaques that were subsequently inoculated with pathogenic SIVmac251. Data on pre-SIV infection samples shown. Representative overlay histograms are shown in the top panel for expression of surface CD4 (a), intracellular CD69 (b), and intracellular CD154 (c) on CMV-specific CD4+ T lymphocytes (solid histograms) and total CD4+ T lymphocytes (open histograms). The bottom panels show the peak channel fluorescence of CD4 (a), CD69 (b), and CD154 (c) on CMV-specific and total CD4+ T lymphocytes in individual rhesus macaques. ND, no data.](http://journals.asm.org/)

proliferative ability has been described in chimeric mice with antigen-specific precursor frequencies high enough to impose constraints on proliferation; in this model noncytolytic antigen-specific CD4+ T cells can synthesize IFN-γ (19).

In conclusion, we have adapted the precise techniques of ELISPOT and intracellular cytokine staining to enumerate and analyze CMV-specific CD4+ T lymphocytes in rhesus macaques. Using these techniques we report the novel finding of a decreased frequency of CMV-specific CD4+ T lymphocytes in association with increased CMV viremia in SIV-infected rhesus macaques. The ability to determine the phenotype of antigen-specific CD4+ cells by flow cytometry has facilitated the characterization of CMV-specific CD4+ T lymphocytes in rhesus macaques and enabled study of factors predisposing to their selective loss after SIV infection. These techniques provide a powerful tool for future prospective studies on CMV pathogenesis in the rhesus macaque animal model of AIDS.

ACKNOWLEDGMENTS

This study was supported by Public Health Service grants RR00168 and AI43890 (A.K.) and AI45314 (R.P.J.).

We gratefully acknowledge Peter Barry for providing plasmid with the rhesus CMV immediate-early gene insert and polyomonal rat anti-rhesus CMV IE1 antibody; Danny Silva for the preparation of rhesus CMV antigen; Dan Shaffer for the design of primers and probe anti-rhesus CMV IE1 antibody; Danny Silva for the preparation of the characterization of CMV-specific CD4+ T lymphocytes in rhesus macaques and enabled study of factors predisposing to their selective loss after SIV infection. These techniques provide a powerful tool for future prospective studies on CMV pathogenesis in the rhesus macaque animal model of AIDS.
